After a journey of twenty-five to thirty days from Wady Halfa, partly in boats, but chiefly on camels, the traveller reaches Khartoum, the capital of Nubia, and the seat of government of the "provinces of the Soudan." The town contains about 30,000 inhabitants; but with the exception of the governor's palace, and one or two harems connected with it, there are no buildings in it of any importance. The gardens are most prolific: pomegranates, lemons, limes, oranges, grapes, cream-fruit, bananas, prickly pears, figs (two crops), and garden vegetables of great size and luxuriance (salads, cucumbers, potatoes, radishes, &c.), are to be had here in abundance. The trade in gum and slaves is the only very important one. There is also a small export trade in gold, ivory, and ostrich feathers; while glass beads, gunpowder, and Manchester cotton goods are the principal imports of this city, which supplies the vast territories of Sennaar, Darfur, and Fazokl. The net revenue of these provinces is said to amount to from L.200,000 to L.250,000 per annum, which is remitted to Cairo, after deducting the various expenses of government, collection, and of the standing army. The latter consists of 15,000 infantry, 5000 cavalry, and 24 pieces of artillery. The governor enjoys a more than viceregal power;—at once commander-in-chief of the army, and chief judge over these provinces. Latif Pasha, who was the governor in 1850, told the writer that he was in direct or indirect communication with 30,000,000 subjects; but as we found him ignorant of the number of tribes inhabiting the immediate districts

Khartoum.

Nile. round Khartoum, no great reliance can be placed on these figures, except in so far as they confirm all the accounts we have of the immense population of the banks of the White Nile. There is no reason to suppose that these nations are badly governed, though they appear somewhat over-taxed in certain districts; for the rulers of the southern provinces of Egypt are all men of great ability,—and, for Turks, of rare intelligence,—in fact, they have, almost without exception, received these high preferments as a species of transportation for being too European and civilized in their ideas. Latif Pasha was an intimate friend of Linant Bey, Clot Bey, and Lambert Bey, all of whom were in great disgrace, and some of them in the same sort of honourable banishment, during the latter part of the reign of Abbas Pasha, the late viceroy of Egypt.

The city of Khartoum is situated in Lat. 15. 37. N., and Long. 33. E. from Greenwich, within 250 yards of the confluence of the White and Blue Niles, the Bahr-el-Abiad, and the Bahr-el-Azrek. From this point the Nile flows 1500 miles ere it reaches the Mediterranean; and with one exception, that of the small tributary the Atbara or Tacazze (a stream which may be waded across in the dry season), not one drop of water falls into it; while it supplies the innumerable *shadoofs* of Nubia, the thousands of *sakias* which water the land of Egypt, and the hundreds of canals which irrigate the country below Assiout; and, after its long journey of 1500 miles, moving along at the rate of from $1\frac{1}{2}$ to 3 miles an hour, exposed to the evaporating influence of the rays of a never-clouded sun, pours into the sea, through the Damietta and Rosetta branches alone, a volume of water amounting to from 151,000,000,000 cubic metres to 706,000,000,000 cubic metres per diem according to the season.

Cause of the inundation.

The most superstitious and uneducated of the Arabs at Cairo still believe that one drop of water falling upon some particular rock in Abyssinia causes the inundation of the Nile; but the real cause of the annual overflow is well known to be the very heavy rains which take place in the south during the months of June, July, and beginning of August. The traveller, ere he reaches the junction of the two Niles, will have already seen some traces of these heavy falls of rain. In the desert of Baiyouda, 150 miles from the river, the sides of each ridge of ground are marked with miniature river-beds; every little valley has a damp spot, where, for a few weeks, a small lake was collected; and his path is often traversed by deep water-courses, now long since dried up. At Khartoum the rains are described as lasting for four or five weeks without intermission, the streets are turned into rivers, the public square into a lake, and many of the mud-walled houses fall in, though the river does not overflow its bank on that side. In 1850 the Azrek rose at Khartoum as much as 18 inches in one night. Violent as these rains seem to be, there is no doubt that further south they are much more violent, and of much longer duration. The two branches of the Nile rise at about the same time. The Blue Nile, during its tortuous course, is fed by the various streams which flow from the mountains of Abyssinia, and the Atbara collects the rain which falls on the high ground situated to the N.E.; but by far the largest body of water comes down by the White Nile from the marshes and lakes in Lat. 6. to 10. N., and from the original mountain sources yet farther S.

Blue Nile.

The sources of the Blue Nile, or Bahr-el-Azrek, as we know by the discoveries of Bruce, consist of three large springs among some mountains 6000 feet above the level of the sea, situated, according to his calculations, in 10. to 11. N. Lat., and 36. to 37. E. Long.; thence the river flows through the Lake of Izana or Dembea, known to Ptolemy by the name of *Kaloe*, and pursuing a most circuitous course (at one time almost returning to its original source), collects all the streams running down from the mountainous

regions of Gojam, and flowing northward through a series of cataracts or rapids, descends into the district of Fazokl, where the gold mines of the Pasha of Egypt are situated. There, having been enlarged by the influx of the Jumet from the S.W., the river reaches the plains of Sennaar by another series of cataracts and rapids. The natural bed of the river at Khartoum is half a mile in width, and the water in the dry season from 400 to 500 yards wide. In the inundation it rises from 18 to 24 feet in height, and is from 1 to $1\frac{1}{2}$ mile in width. The water flows very rapidly when compared with the White Nile, and opposite Khartoum is clearer, fresher, and sweeter, than after its junction with the latter.

The sources from which we might draw our information **White Nile.** as to the White Nile are very numerous, but as very few of those who have ascended this branch of the Nile above Khartoum have taken reliable observations, and as no two accounts are easily reconciled, our task of selection is no easy one. We shall, however, briefly glance at the travels and opinions of the most trustworthy pioneers.

Browne penetrated to the south of Darfur, and believes **Opinions of Browne.** that the actual sources of the Bahr-el-Abiad are situated in 7. N. Lat., and consist of many streams flowing from the Mountains of the Moon, which he places in 6. N. Lat., 4 degrees N. of the point to which the Nile has since been ascended. This is a revival of the opinion of Ptolemy, and we believe the correct one,—“The Ethiopian Anthropophagi dwell around this gulf, which is skirted on the west by the Mountain of the Moon, from the snows of which the superabundant waters of the Nile are drawn.” (Ptol., *Geogr.* iv. 8.)

Linant Bey, travelling for the African Association in 1827, surveyed the course of the river a direct distance of 132 geographical miles, from Khartoum to about Lat. 10. N. He describes the river as in many places $1\frac{1}{2}$ mile wide, while its banks seemed often as much as 4 miles apart; and asserts that when the river is at its greatest height it overflows its banks a distance of 20 miles on each side. The general appearance of the country is flat; the eastern side is desert, while the western banks are covered with vegetation, stretching inland. Farther south, the river becomes narrower, and the depth increases to from 6 to 8 fathoms. From information obtained at the most southern point of his journey, he seems to be of opinion that the White Nile rises from a system of lakes, and he advances, in defence of this view, two facts,—1st, That neither gravel nor sand, indicative of its being fed by torrents, are found in it, and that the clayey nature of its shoals proves that it does not come from mountains; 2d, That the prodigious quantities of fish which arrive at Khartoum by the first freshes could only have come from lakes, where they had been imprisoned during the low water, and from which they escape when the heavy rains commence.

Mr Hoskins believes that the source of the Nile could **Hoskins.** only be discovered by means of an armed force, and that it would require a large army to subdue the great extent of country through which the Bahr-el-Abiad passes. He thinks that not only the chiefs, but the whole population, instead of any of them joining the standard of the invader, or furnishing him with provisions, would resolutely oppose him; each man would fight for the preservation of his property, family, and liberty.

Colonel Leake observes that, if man-stealing had not been the principal object of the numerous Egyptian expeditions up the White Nile, they would have been more successful in penetrating to its sources. He seems to be of opinion that a route by water in the direction of the sources of the Nile is afforded from the westward by means of the newly-discovered branch of the Quorra (the Shary), which is a mile and a half wide at its junction with the Quorra, and is navigable for a great distance above the confluence.

Colonel Leake.

Nile.

As the Shary, where crossed by Dr Barth, in Lat. 9. 2. N., Long. 14. E., was found to be about half a mile wide, this hypothesis is not an unnatural one. The most ancient authorities uniformly maintain that the Niger and the Nile are connected together; and it has ever been a favourite opinion with the Egyptian race that the Nile flows from the sea through the centre of Africa, is lost in the sands of the great desert, and re-appears in the country of the Shellucs.

Werne.

Mr Werne, in his work on the White Nile, gives a most detailed account of his travels southward to about 4. 30. N. Lat. He formed part of the great expedition in 1840 of which Ahmed Pasha and Suliman Kashef were the chiefs, and MM. Arnaud, Thibaut, and Sabatier the principal Europeans. The expedition consisted of 10 vessels mounting 10 guns in all, and manned by 260 Negro, Egyptian, or Syrian sailors and soldiers. They set sail for the southwards from Khartoum on the 23d November 1840. As they proceeded, they found the left shore wooded with a girdle of copsewood and large trees, extending just as far as the annual inundation; while on the right shore the bare stony desert extended to the horizon. In Lat. 14. 35. N. the river, now 3 miles broad, becomes studded with fertile islands. They sail past the islands of Genna, Sial, and Salahieh, swarming with three distinct tribes of monkeys; in the mud where they anchor, large river snails and oysters are found; the low banks of the islands are trampled with hippopotamus footprints; among the trunks of the trees, still standing in the water, large white aquatic flowers glisten, and the beautiful double lotus, sacred to the temples of Lower Egypt, here first appears; the sun sinks behind the mountains of Hassanieh, and the roar of the lion resounds on the eastern bank.

Twelve days' sailing brings them to where the great population of the banks of the White Nile begins. At one moment 15 to 18 villages, with their round mud houses, each containing from 6 to 8 inhabitants, are in sight; a few minutes after, a bend of the river opens 20 to 25 more to the view—many of them containing from 200 to 300 houses. As far as the eye can reach, vast fields of corn stretch to the eastward, speckled with habitations; while the western side continues flat, and forms an immeasurable grassy sea, the limit of which is undiscernible from the masthead. A few hours farther on, they sail through a perfect sea of lotus, the whole river for many miles being white with these beautiful flowers. Flocks of guinea-fowls fly overhead, and geese, ducks, and many varieties of fresh-water fowl abound. They proceed past forests of tamarisks and lately covered pasture land, thickly peopled with the dark handsome Shelluc or Bakhara tribes, to where (Lat. 10 N.) the river winds in two vast streams round a large island of marshy meadow land, 6 miles from side to side, and nearly 20 long—forming no doubt the bed of the river in the inundation season. When again on the united stream, they find the number of villages undiminished, but they are now shaded by the African giant-tree (*Adansonia digitata*), and in the woods the gum-bearing mimosa seems crushed by the slender aspiring Dhelleb palm, here taking the place of the Doum palm of Berber. At one moment six ostriches are in sight on the western bank, and sixteen white crocodiles are seen basking on the mud islands in the middle of the stream. As they reach the River Saubat (Lat. 9. N.), near the mouth of which 17 new Shelluc villages appear, they see a large city 9 miles off, on the confines of a fertile grassy plain, covered with huts and cattle. On the western bank, two giraffes are quietly browsing; and 35 villages, containing from 120 to 600 inhabitants each, are remarked at one moment.

Marshes.

In Lat. 9. 4. N. all this population and fertility ceases, and the marshes begin. The bottom of the river is covered with black moss, the current falls to half or even a quarter of a mile an hour, and the air is alive with every species

of mosquito and gnat; not a breath of air fills the sails; the heat is most oppressive, every sign of firm ground vanishes, no tree, no village is in sight, and for days they row on in a sea of grass, the burning sky above them. The only sounds are the trombone gruntings of the numerous hippopotami, as they wallow among the dank grasses. The gnats are merciless—no protection from them can be devised, and there is no rest night or day from their attacks; sickness appears—many of the crew die, and Mr Werner is himself insensible for four days. The papyrus, 15 to 20 feet high, and 2 inches thick, bearing on the top a corolla or tuft, branching out in rays, as depicted in the temples, though found in no other part of Egypt, is abundant here. This is the part of the journey up the White Nile which has proved fatal to the success of so many expeditions. The crews have generally revolted, and refused to proceed any farther, or the chiefs of the party have fallen ill, and ordered a return.

At last they emerge into a canal 100 yards broad, surrounded by high reeds; the banks seem to be of a soft green colour, formed by pale green aquatic plants—lilac convolvulus, moss, water-thistles, and a kind of hemp—in which the yellow ambac tree flourishes, hung round with luxuriant deep-yellow creepers. Few land birds are to be seen, but the pelican, the black ibis, and the dark-red stork are not uncommon. The river winds so much (Lat. 7. 48. N.), that a boat which is four hours ahead seems to be moving along parallel with the rest of the expedition, and the progress is thought good when they make 2 miles due south in 24 hours. Again (Lat. 6. 42. N.) villages appear, and city succeeds city in the pasture land in the interior on both sides of the river, and the shores are lined with an innumerable population. A small army of elephants, with the white paddy birds sitting on their backs, are shaking the branches of the Dhelleb palm for its fruit; and the giraffe watches them from the borders of the desert.

Shortly after entering the kingdom of Bary the expedition was guilty of a rash brutality, which, had there not been a good wind at the time, enabling them to push forward, might have led to the most disastrous consequences. The Turks quarrelled about some exchanges with the defenceless natives, and fired among them, killing and wounding 20 or 30 men and women. The natives are of course not able to distinguish between the Turkish soldiery and Europeans; and as each Turkish expedition robs and murders without scruple, the natural timidity of the Negroes daily increases, and thus casts further difficulties in the way of peaceful traders. The European portion of the expedition seem to have behaved pretty well towards the natives, but were, as we see from the three published accounts, quarrelling with one another the whole time, and would never have proceeded as far southwards as they did, had they not been under the command of a stolid, obstinate, and indifferent Turk. From Lat. 6. to Lat. 4. 30. N., the river winds among fertile fields covered with habitations, and the horizon is bounded on the east, west, and south by high mountain-ranges—the Alps of Central Africa. In 4. 30. N. Lat., on the sixtieth day's sail from Khartoum, their progress was arrested by ridges of gneiss rock running across the river, and forming a rapid not unlike the second or third cataracts in Nubia, and which it would have been in vain to attempt to pass without unloading their *diabehies*. In a country rendered hostile by their own misdeeds, this would have been very dangerous; and having stayed at this point for three days, they made sail northwards. The river was at this point 323 feet across, and seemed to stretch S.S.W.

During their stay, Lakono, the King of Bary, one of the most powerful rulers of Central Africa, and his wife, paid a visit to the commander, Selim Capitan. He arrived escorted by about 1500 Negroes, all armed, naked, painted

Nile.

Nile. red with ochre, and wearing plumes of ostrich, guinea-fowl, or cocks' feathers among their hair. Lakono wore a long and wide blue cotton shirt, and on his head an oval network cap covered with black ostrich feathers; his neck, arms, and legs were ornamented with rings of iron, red and yellow copper, ivory, and glass beads. In height 7 feet; the face oval; the forehead arched; the nose straight or curved, with rather wide nostrils; the mouth full, like that of the ancient Egyptians, as sculptured in the temple of Aboosimbel; the orifice of the ears large; and the temples a little depressed: he may be taken as a type of his tribe. His queen was most simply attired in two red leather aprons; the head was close shaved; and she wore her usual ornaments of iron, copper, and ivory round her neck, arms, and ankles. The king, and indeed most of the court, towered above the heads of their Turkish and Christian entertainers, being all from 6 feet 6 inches to 7 feet high.

This tribe do not believe in a future life, but acknowledge one great invisible spirit, the creator of all things. They believe that he sometimes visits a particular tree or rock in the shape of a bird or lizard, and here a dervish or hermit priest dwells, to whom the tribe come, laden with presents, to consult as to their domestic, commercial, or warlike affairs.

Lakono told Mr Werne, that in thirty days (travelling) from this point, the Abiad separates into four shallow arms, and the water only reaches up to the ankles; but whether these four brooks flow from the mountains or spring from the ground, he could not say. He seemed positive that there was no snow on these mountains, and they had great difficulty in making him understand what snow was. This seems to upset the theory that the *melting of the snow* on the mountains is a cause of the inundation.

On the 28th of January the expedition began their return, and after eighty-three days' sail they arrived at Khar-toum.

M. Rollet. M. Brun Rollet, whom the writer of this article had the pleasure of seeing in Khartoum, has on several occasions penetrated as far as the 5th and 6th degrees N. Lat., and once reached the mountain of Garbo (3. N. Lat.), the highest point to which the Nile has been ascended.

From this place (he says) there is every reason to believe that the river, becoming less and less, could be traced about 3 or 4 degrees to the southward, to the foot of the mountains of Komberat, on the equator. The Kuendas, inhabitants of these latitudes, say, that from this chain of mountains flow two small streams which unite in the village of Lokaya, S. of Robenza, at which spot the river may be crossed on the trunk of a fallen tree. These natives could not be made to comprehend what snow was.

Trade. M. Rollet has devoted himself for many years to trading with the natives on the banks of the Misslad or Keilak, Saubat, and White Nile. Adopting their costume and speaking their language, he has resided among them year after year, exchanging beads and iron, against gum, ivory, and gold-dust. He has a very high opinion of most of the tribes with whom he came in contact, and believes much in the value of the commercial relations which might be established with them. Once promote commerce (says M. Rollet), by protecting the navigation of the river and the property on the banks, and vast pecuniary advantages would accrue to the Egyptian government; for the three principal tributaries of the Nile are navigable almost to their sources. By the Saubat, the foot of the mountains of Imadon, on the southern confines of the kingdom of Cafu, may be reached; there a large trade in ivory, gold-dust, gum, cotton, and feathers, might be established with the nations living on the banks of the river, the Gallahs, and the tribes living to the S.E. of the Adehs.

The exchange of iron for ivory, which amounted to 20 tons in 1845, has risen to 100 tons in 1851; the export of

gum has increased much more. When once the Keilac has been ascended to Lake Fitry, will not (asks M. Rollet) the route of the White Nile monopolize and treble the vast export and import trade which has now to pass through the great desert from the sea at Tripoli and Morocco to Bornou, Ouaday, and Bagharmi? The cataracts of the lower Nile will always prove a barrier to any very large extension of commerce, but a railway from Assuan through the desert of Korusko would bring those rich countries to within ten days' journey of Cairo. All these vast tribes—the Denkas, Shellucs, and Barys—would sooner or later become tributary to Egypt, the slave trade raging between them would be abolished, and the ancient country would regain the high rank which she enjoyed under the most powerful and prosperous of the Pharaohs. If this sounds enthusiastic, we must remember that these are the opinions of a quiet middle-aged man, a clever and successful merchant, who has lived for twenty years in Southern Africa engaged in the trade, and living among the people of whom he speaks.

Much hope was entertained by all those who are interested in the subject, either on commercial or on geographical grounds, of the success of the great expedition for the discovery of the sources of the Nile, which left Cairo last spring with flat-bottomed steamboats, and all necessary appurtenances; but the premature return of Mr A. W. Twyford, the only Englishman of the party (June 1857), with the news that the expedition was stopped by orders from Said Pasha at Meroë, near the Fourth Cataract, has disappointed all the expectations that had been formed.

The source of the Nile is therefore still unvisited; but after reading the interesting travels of Messrs Werne and Rollet, we can almost answer the question asked by Tibullus 1400 years ago—

“Nile pater quanam te dicere causa?
Aut quibus in terris accoluisse caput?”

We may assume that the sources of the Nile consist of two or more mountain streams, flowing from the mountains of Kombirat, on the equator, or half a degree south of it; thence it flows northward to Lat. 9. N.; there it receives the tributary streams of the Misslad or Keilak from the westward, and the Saubat from the eastward; thence, stretching in a north-easterly direction, it reaches the city of Khartoum, about 1500 miles from its source, where it is joined by the Bahr-el-Azrek, or Blue Nile; a few miles further on it is increased by the waters of the Atbara, whence it flows onward through Nubia; thence past the First Cataract into Upper Egypt at Assuan, past Cairo to the Barege; whence, diverging into two great branches, it falls into the Mediterranean through the Damietta and Rosetta mouths.

The writer of this article has drawn his information from personal observation, and from the following works, especially from the last three named:—Miss Martineau, *Eastern Life*; Captain Neel, *Nubian Desert*; Wilkinson, *Modern Egypt*; John Kenrick, *Ancient Egypt*; Clot Bey, *Aperçu Générale sur l'Égypte*; *Journal of the Geographical Society*; Hoskins, *Travels in Ethiopia*; A. Melly, *Lettres d'Égypte et de Nubie*, 1852; M. Brun Rollet, *Le Nil Blanc et Le Soudan*, Paris, 1855; Ferdinand Werne, *Expedition to discover the Sources of the White Nile*, London, 1849. (G. M.)

NIMEGUEN, or NYMEGEN, a town of Holland, in the province of Gelderland, stands on the Waal, 10 miles S.S.W. of Arnheim, and 53 S.E. of Amsterdam. It is surrounded by fortifications in the form of a crescent, and entered by ten gates. The church of St Stephen is a Gothic edifice in the form of a Greek cross, and contains some interesting monuments. There is also a town-hall, built in 1554, in the *Renaissance* style, and adorned in front with statues of the German emperors who have conferred benefits on the town. In this hall was signed the treaty of 1678 between Louis XIV., Charles II. of

Nimes
||
Nineveh.

Spain, and the Dutch States. On a hill near the town are a few remains of the castle of Valkenhof, said to have been built by Julius Cæsar, and occupied by Charlemagne. Nimeguen has numerous churches, an hospital, military watch-house, barracks, arsenal, theatre, and prison. There is a large market-place; and on an eminence stands the Belvedere, a lofty summer-house built by the town, and commanding a fine view. Nimeguen is famous throughout the Netherlands for beer; and it also manufactures leather, hardware, stoves, glue, Prussian blue, soap, painted glass, &c. There is a harbour in the river protected by a wall; and a considerable transit trade is carried on. Pop. (1850) 21,272.

NIMES. See NISMES.

NINEVEH (Heb. נִינְוֵה; Gr. Νῆβος, Νῆβελ; Lat. *Ninus*,

Ninos, *Nineve*; Arab. نَيْنَوَى; in the Assyrian cuneiform character probably   , *Ninua*; or (?) sometimes

 , the capital of the ancient Assyrian empire. It stood upon the eastern bank of the Tigris, but its exact site had not been satisfactorily determined until recent excavations had laid bare some of its principal ruins. Tradition, however, had attached the name to a considerable group of mounds, supposed, until lately, to be mere heaps of earth and rubbish, near the Arab town of Mosul. Nineveh offers almost a solitary instance of a great and renowned city having entirely passed away previously to what may be termed the historic period. It did not survive the empire of which it was the capital. Both perished together about a century and a half before the birth of Herodotus, the father of history. Even the very ruins of its great national monuments seem to have disappeared before any pen could describe them. The Greek geographers collected some fabulous stories concerning the magnitude and duration of the empire, and the extent and magnificence of the capital; but the only contemporary notice of either is to be found in the Bible, and the details afforded by the Sacred records are few and meagre. It is, however, its connection with the Jews, with the fulfilment of prophecy, and more especially with the events of the first Captivity, that renders the history of Nineveh of so much interest.

The earliest biblical mention of Nineveh is to be found in the 10th or genealogical chapter of Genesis. It is there placed among the primitive cities built after the dispersion of mankind, and its foundation is attributed to Nimrod or to Asshur, according to the different reading of the Hebrew text, which leaves it somewhat in doubt whether the latter name applies to an individual or to the country of Assyria. It would appear from the context that the Jews believed it to have been built and inhabited by the same race that raised Babylon, from which city the Ninevites were a colony. The next allusion to it, according to the generally received chronology, would be in the book of Jonah, B.C. 850; but some German critics have shown that that narrative could scarcely have been compiled earlier than the fifth century B.C., and consequently long after the destruction of the city. It is there described as an "exceeding great city, of three days' journey," containing "more than six score thousand persons that cannot discern between their right hand and their left, and also much cattle." Nahum, when foretelling its approaching fate, about 720 B.C., alludes to its vast riches of silver and gold (ii. 9), and the multitude of its great men and merchants (iii. 16, 17). It is next mentioned in Isaiah as the residence of Sennacherib, the King of Assyria, about 710 B.C. Zephaniah prophesies its impending ruin; and this is the last allusion to it we find in Scripture as an existing city. In the apocryphal books it is spoken of as the dwelling-place of Tobit and his family, and in Judith as the capital of Nebuchodonosor, King of Assyria.

Zephaniah prophesied in the reign of Josiah, the date

of whose death may be fixed about 609 B.C. Jeremiah (xxv. 18–26) enumerating, in the first year of the Captivity, or about 605 B.C., "the kings of the north far and near, and all the kingdoms of the world," omits from the list Assyria and Nineveh. It has been presumed, therefore, that both empire and city had ceased to exist, and that their fall had taken place between 609 and 605. This date is remarkably consistent with the statement of Herodotus, that Cyaxares conquered the Assyrians after the expulsion of the Scythians from Western Asia,—an event which did not occur, according to the most accurate computation, until 606 B.C.; the precise date which may therefore be assigned with some confidence, as founded upon the concurrent testimony of sacred and profane history, to the ultimate destruction of Nineveh. (Clinton, *Fasti Hellenici*, i. 269.) It would appear, however, from the statements of Greek writers, that about two centuries and a half before that period the city had been devastated, if not destroyed, by Arbaces, King of the Medes, upon whose successful invasion of Assyria, Sardanapalus, the last monarch of the ancient Assyrian dynasty, burnt himself with his wives and riches on the funeral pile, according to the well-known Greek legend. Although Abydenus places this event 67 years before the first Olympiad, or 843 B.C. (Euseb. *Chron.* i. 12), it has been confounded with the final overthrow of the empire, which occurred 237 years later, upon the invasion of Assyria by the combined armies of Cyaxares, King of Persia and Media, and Nabopolassar, King, or more probably Satrap, of Babylon, who had rebelled against the King of Assyria. Many ancient writers bring the Assyrian empire to a close with the death of Sardanapalus. To reconcile this confusion of dates and events, it has been conjectured that there were two kings of the same name, and that the second Sardanapalus, who was also called Saracus, was the last of the second dynasty, and, like his predecessor, destroyed himself with his palaces and wealth when his capital was about to fall into the hands of his enemies. Josephus, on the other hand (*Ant.* ix. 11, 3), distinguishes between the extinction of the Assyrian empire and the fall of Nineveh; the latter he places 115 years after the date of Nahum's prophecy, or about 626 B.C.; the former (x. 2, 2), in the reign of Hezekiah, probably on the murder of Sennacherib by his sons, or 710 B.C. Hitherto the discoveries amongst the ruins of the city, and the interpretation of the cuneiform inscriptions, have furnished no evidence of any conquest of Assyria by a foreign race corresponding with the statements of the Greek historians and of Josephus, although there is reason to believe from the monuments that a change of dynasty took place about 750 B.C. It may therefore be presumed that the supposed destruction of Nineveh by Arbaces refers rather to a revolt of the Medes, ultimately suppressed, with which it has been confounded, than to a revolution causing the overthrow of the empire and an organic change of government. The whole question is involved in so much obscurity, that it can scarcely be determined by any attempt, however ingenious, to reconcile the conflicting statements of Greek writers. A better acquaintance with the contents of the cuneiform inscriptions can alone afford authentic information upon this subject.

The earliest mention of Nineveh after its fall is to be found in the Greek geographers. Herodotus, B.C. 440, alludes to it, when describing a canal connecting the Euphrates with the Tigris, as having stood upon the banks of this latter river (i. 193); and again mentions it casually in his sketch of Assyrian history. He evidently speaks of it as no longer existing in his day. As he gives so ample a description of Babylon, and as, in his journey thither, he probably descended the Tigris, and must have passed the very site of the sister city, it is to be presumed that he would have left some account even of any ruins that might have

Nineveh

Nineveh. been still standing. The supposition that Nineveh had been entirely destroyed and deserted by its inhabitants long before his time, and had not been rebuilt, is confirmed by the fact, that Xenophon does not even mention the name of Nineveh, although, when leading the Ten Thousand in their memorable retreat through the Assyrian plains forty years later, he actually marched over the ground on which the city once stood; a remarkable circumstance, considering the important part Nineveh had played in the history of Asia. He describes, however, a large uninhabited castle, the walls of which consisted of a plinth 50 feet high, and as many broad, built of polished stones full of shells, and supporting a superstructure of brick masonry of the same breadth, but double the height. He gives no name to these ruins, although they were actually the walls of part of the ancient city of Nineveh, merely observing that they were near a Median town called Mespila, also, it would appear, uninhabited. Some similarity in the name has suggested the identification of this place with Mosul, which stands on the western bank of the Tigris, immediately opposite the remains described by the Greek commander.

Ctesias, who was Xenophon's contemporary, describes the city as one which had never been exceeded in the extent and magnificence of its walls, but makes the strange blunder of placing it on the Euphrates (*Frag.* i. 4), in which he has been followed by Diodorus Siculus (ii. 27, 28), and which can only be accounted for on the supposition, either that the city had completely disappeared, or that an error had crept at a very early period into the original text. A fragment from Ctesias, preserved by Nicolaus Damascenus, restores the city to its true site on the Tigris (K. O. Müller, *Frag. Hist. Græc.* iii. 858).

About seventy years after the retreat of the Ten Thousand, Alexander fought his great battle of Arbela near the village of Gaugamela, almost within sight of the very ruins described by Xenophon; yet none of the historians of his campaigns ever allude to them, or mention the name of Nineveh. Strabo, Diodorus Siculus, Ptolemy, and other writers, only refer to the city as having been the capital of the extinct Assyrian empire, or describe some of its monuments from traditions preserved in earlier records. We may therefore conclude that Nineveh was not only entirely deserted and destroyed after its capture by the Persians and Babylonians, but that no attempt was made to rebuild or re-occupy it. Indeed, its position was not such as to render it important as a centre of trade or traffic. It could only have risen to greatness and wealth as the capital of an empire and the seat of government. When Babylon usurped those honours, a busy population was no longer attracted to Nineveh.

Some centuries later, however, a small fortified town, probably of Parthian origin, seems to have been built on the ruins of the ancient city, and to have been even called by its name. From the numerous Roman and Parthian remains, such as fragments of terra cotta figures and coins, found in the rubbish which had accumulated over the Assyrian ruins, we may suppose that it stood on one of the great mounds opposite Mosul. Ammianus Marcellinus (xxiii. 20) mentions "Nineve," and Tacitus (xii. 3) alludes to the capture of "Ninos" by Meherdates. It became incorporated at one time in the Roman empire; and two Roman coins are known to have been struck there; one of Trajan, with the legend AUG. FELI. NINI. . . . CLAV, the other of Maximinus, with the legend COL. NINIVA. CLAVD. It would seem, from the epithet "Claudiopolis," that the new town had been restored or rebuilt under the Emperor Claudius. (Layard, *Nin. and Bab.* 591.) It appears to have also borne at one time the name of Hierapolis. In a tomb, probably of Parthian origin, found amongst the ruins, was preserved a gold coin of the Emperor Maximinus.

A small village called Ninoua is mentioned both by the
VOL. XVI.

Nineveh. Arab geographers and by European travellers as standing on the site of Nineveh in the middle ages. Both village and name have long since disappeared. The tradition of the site of the ancient city is, however, still preserved by the few Christians who live around the ruins, and by the Mohammedans in their peculiar veneration for an edifice supposed, but without any reason whatever, to cover the tomb of Jonah, built over one of the principal buried ruins, and probably upon the foundations of an early Christian church or monastery dedicated to the prophet. The great mound opposite Mosul on which the Roman or Parthian fortress of Ninos is supposed to have stood, is now called by the Turks *Kouyunjik*—i.e., "The Little Sheep;" by the Arabs, *Armousheeah*. The origin of both names is unknown.

The ruins opposite Mosul have been mentioned by most travellers, ancient and modern, who have visited that town; but the first to give any accurate description and plan of them was Mr Rich, for some years political agent of the East India Company at Baghdad. In the year 1820 he was able to make a careful survey of them, which was subsequently published by his widow. The Arabs in the neighbourhood informed him that some time previous to his visit the figures of men and animals sculptured in stone had been dug out of one of the mounds. They had been immediately destroyed by the Mohammedans as idols belonging to the infidels, and Mr Rich was unable to obtain even a fragment. He only succeeded in collecting a few specimens of pottery and bricks inscribed with cuneiform characters, and one or two Assyrian relics. Ruins similar to those examined by Mr Rich abound in the region watered by the Euphrates and Tigris. They consist of enormous mounds of earth rising abruptly from the plain. At some distance they appear like natural elevations or mere heaps of earth; it is only on closer inspection that they are found to be the work of men's hands. Where the winter rains have worn deep furrows in their sides, may be traced masses of solid masonry, either of bricks baked in the kiln, or simply dried in the sun. On and around them, far and wide, are scattered fragments of pottery, the sure sign of former population. The Arabs not unfrequently choose these artificial elevations as the site of their villages of rude mud huts, either building upon their summit, as a position easy of defence against marauding Bedouins, or at their foot. They call them *Tel*, a name by which they appear to have been known even in the time of the Jewish captivity. The principal mounds of this description on or near the site of Nineveh are those already mentioned near Mosul, usually identified with the remains of the city;—Nimroud, near the junction of the Rivers Tigris and Great Zab, about 20 miles to the S. of Kouyunjik; Selamiyah, 3 miles to the N. of Nimroud; Khorsabad, 12 miles to the N.E. of Mosul; and Karamles, about 15 miles to the N.E. of Nimroud. The space between these ruins contains numerous smaller mounds covering the remains of ancient edifices; and on all sides may be found the traces of former habitations. The groups of Kouyunjik, Nimroud, Selamiyah, and Khorsabad, are remarkable as each comprising one or more large mounds, and the remains of a regular system of walls and defences inclosing a considerable area. The other ruins are isolated and scattered over the face of the country without apparent order or design.

In the year 1841 M. Botta, who had been recently appointed French consul at Mosul, determined to examine more carefully than had hitherto been attempted the mound of Kouyunjik. For this purpose he employed a party of Arabs to excavate in it, but without other result than the discovery of a few fragments of inscribed slabs. A peasant having informed him that remains of ancient buildings had been found at Khorsabad in digging the foundation of a house, he removed his workmen to that ruin. He was

Nineveh. almost immediately rewarded by the discovery of a series of upright slabs in a coarse grayish alabaster, sculptured in bas-relief, with figures of men and animals, and with inscriptions in the cuneiform or arrow-headed character, then only known from Persian monuments of the Achmenian dynasty, and a few fragments from the ruins of Assyria and Babylonia. These slabs were found to be the panelling of the lower part of a room filled with earth and rubbish. A doorway opened into a second apartment, and further excavations disclosed a series of halls and chambers of different dimensions lined with similar sculptured slabs. After some months' labour, the greater part of the ground plan of a magnificent palace was laid bare.

This edifice had evidently been destroyed by fire, which had calcined the alabaster slabs. A mass of charred wood, bricks, and other materials, employed in the construction of the building, completely covered the ruins. Above this heap of rubbish soil had accumulated. The surface of the mound yearly produced a crop of barley or corn, and on one part stood a small Arab village. The huts were purchased, and pulled down. Subsequently, under the directions of M. Place, the ruins of a propylæum and of a broad flight of steps leading up to the building were uncovered.

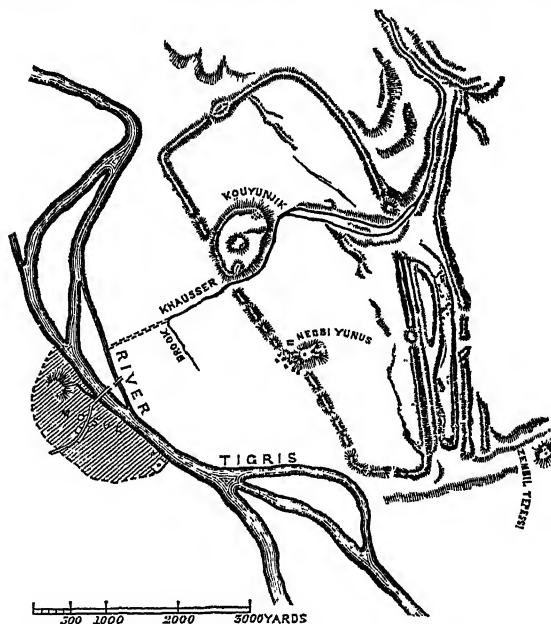

The principal mound at Khorsabad may be divided into two parts; an upper, about 650 feet square, and 30 feet high; and a lower, connected with it, about 1350 feet by 300. At one corner it is a low pyramidal elevation, which may mark the remains of a watch-tower or the superstructure of a royal tomb. The entire quadrangle, inclosed by walls, would be about $1\frac{1}{2}$ mile square. It contains no other ruin of any importance.

M. Botta's discoveries at Khorsabad were followed by those of Mr Layard at Nimroud, where ruins of a similar character, though of greater antiquity and of more importance, as being the remains of buildings of several different epochs, were uncovered. A mound 700 yards by 400, surmounted by a conical elevation or pyramid 140 feet high, forms the corner of a walled inclosure 2331 yards by 2095 in the widest part. The Tigris once flowed under the western face of this quadrangle, and at the foot of the great mound. It is now $1\frac{1}{2}$ mile distant. The northern wall still shows the remains of fifty-eight nearly equidistant towers; in the eastern only fifty can be traced. A deep ditch or moat appears to have defended such parts of the inclosure as were not protected by the river. The remains of several distinct buildings, erected by different kings, were found in the principal mound. In one instance, materials, such as sculptured slabs, had been taken from one edifice to be used in the erection of another. Some had been destroyed by fire, others appeared to have been suddenly covered by the falling in of the upper stories. In the one case, the sculptures were calcined, as at Khorsabad; in the other, they were perfectly preserved with all their original sharpness and minute details. Many of the chambers were panelled with slabs having nothing but the same inscription repeated over and over again. Others were lined with bas-reliefs singularly interesting and elaborate. The pyramid was found to be the remains of a square edifice, solidly constructed of sun-dried bricks, faced to the height of 20 feet with masonry of large stones carefully squared and bevelled, and above that height with kiln-burned bricks. In the interior was discovered one vaulted gallery 100 feet long, 12 high, and only 6 broad. It was probably a royal sepulchre, but had been despoiled at some remote period of its contents. It has been conjectured that it may represent the tomb of Sardanapalus, which the Greeks described as placed at one of the entrances to the city. No remains of modern habitations existed in any part of the ruins. A small Arab village, named after them, has been built about one mile from the great mound.

Excavations were also carried on by Mr Layard in the

ruins opposite Mosul, which consist of two principal mounds, Kouyunjik, and that of Nebbi Yunus (or the tomb of the prophet Jonah). On the sides and at the foot of the latter, facing the river, is an Arab village, and the summit is covered with the graves of Mohammedans who have been buried around the holy edifice. A village formerly stood on Kouyunjik, but its inhabitants deserted it many years ago, and established themselves in the plain beneath. The two mounds form part of the western or river side of the fortified inclosure. Kouyunjik, the largest, measures about 866 yards by 500; Nebbi Yunus, 566 by 400. They are connected by the remains of part of the wall forming the western face of the quadrangle, which is 4530 yards in entire length. The northern wall is 2330 yards; the eastern, which forms a considerable curve, is about 5300; whilst the southern is scarcely 1000; the inclosure having thus the form of an irregular quadrangle, approaching to a trapezium. The northern face was defended by a deep

Nineveh.

moat; the western was protected by the Tigris, which washed the walls, but has long since deserted its ancient bed, and now flows about three-fourths of a mile from Kouyunjik; still, however, approaching the north-west corner of the inclosure. On the southern face was a ditch and an exterior rampart. The eastern face, being the most exposed, was the most strongly fortified. For this purpose the nature of the ground offered many advantages. The Khauser, a deep, sluggish stream, divides the quadrangle into two nearly equal parts, and winds round the base of Kouyunjik. Before entering the quadrangle, it runs for about $1\frac{1}{4}$ mile parallel to and near the wall, thus furnishing a strong natural defence. A low ridge of conglomerate rock beyond the Khauser was heightened, by artificial means, to form strong outer ramparts. The fortifications to the south of the point where the Khauser enters the inclosure were very extensive and complete. Two deep and broad ditches, fed by that stream, one dividing itself into two branches, and the outer and larger moat being no less than about 200 feet in width, were separated by a second wall or rampart; whilst a third, still in some places about 100 feet high, faced the open country, and extended almost the entire length of the quadrangle. This outer wall was probably that described by Diodorus Siculus as 100 feet high, and sufficiently wide for three chariots to drive abreast upon it. Its length he absurdly exaggerated. It appears to have been constructed chiefly of the earth and rubbish

Nineveh. removed to form the ditch.' No remains of stone facings have been found. The inner wall was built of stone and brick masonry. It no doubt resembled those of the fortified cities represented in the Assyrian bas-reliefs, with towers at equal distances (many may still be traced), and surmounted by ornamental battlements of stone, portions of which have been found among the ruins. The entrances or gateways were probably arched; two have been discovered and partly excavated, one nearly in the centre of the northern, the other in the inner eastern wall. The former consisted of two halls, 70 feet by 23, opening upon the plain, and upon the interior of the inclosure by gateways flanked by colossal man-headed bulls and winged human figures. On the pavement of limestone slabs could still be traced the ruts of the chariot wheels. From the immense mass of bricks, charred wood, and rubbish in which this gateway was buried, it may be conjectured that a lofty tower rose above it, which, like the palace, was destroyed by fire.

The ruins of the palace at Kouyunjik are similar to those at Nimroud and Khorsabad, but belong to an edifice of greater extent and magnificence than either. The dimensions of the principal courts or halls exceed those of any other Assyrian building yet discovered. Every part of the palace was adorned with sculptures. During the excavations carried on by Mr Layard no less than 71 chambers, panelled with nearly two miles of bas-reliefs, and 27 entrances formed by colossal winged bulls or lion sphinxes, were uncovered, and scarcely half the palace was examined. Works since carried on under the superintendence of Mr Hormuzd Rassam and of Mr Loftus have brought to light a large number of additional apartments.

The sanctity attached by the Mohammedans of Mosul to the tomb of Jonah, has prevented Europeans from exploring to any extent the mound upon which it stands. Remains of building resembling those at Kouyunjik, and of nearly the same period, were, however, discovered in it by Mr Layard; and subsequent excavations on a small scale, undertaken by the Turkish government, have proved the existence of a palace adorned with sculptures and sphinxes.

The ruins of a palace or temple have also been discovered in the mound of Shereef-Khan, about $5\frac{1}{2}$ miles to the north of Kouyunjik; and nearly all the mounds scattered over the plain between the Tigris and the hills have, when examined, been found to contain remains of edifices, but none have furnished sculptured or inscribed slabs. The principal ruins in the district are,—Selamiyah, three miles north of Nimroud, with a walled inclosure about three miles in circuit; Karamles (near the field of the battle of Gaugamela or Arbela); Baashiekha; and Baazani.

The most ancient Assyrian edifice hitherto discovered is that at the north-western corner of the mound of Nimroud. It appears to have been rebuilt, if not founded, by a king whose name is believed, by some interpreters of the cuneiform character, to read Asshur-dan-pal, and to correspond with the Greek Sardanapalus. The approximate date of his reign may be from 950 to 920 B.C. His son, whose name is read Shalmanee-bar, erected a second palace in the centre of the same mound. His grandson (? Phalukha), who is identified with the Scriptural Pul, and whose queen is supposed to have been the celebrated Semiramis, her name having been found on monuments from this building, rebuilt this edifice, and founded a third near the spot.

The next palace in order of date is that at Khorsabad, raised by a king who has been identified with the Sargon of Isaiah (xx.), and who would have consequently reigned

about 725 B.C. The ruins of this building were called, after him, Sarâoun even long after the Arab conquest. The great palace excavated at Kouyunjik was founded by Sennacherib about 700 B.C., as well as those at Shereef-Khan and at Nebbi-Yunus, the latter of which appears to have been finished by his son Essarhaddon, who added an additional edifice to the group already erected at Nimroud, and for this purpose appears to have destroyed, or taken materials from, those built by Sardanapalus, by the Tiglath-pileser of Scripture, and others, his predecessors. The son of Essarhaddon, whose name also has some resemblance to Sardanapalus, completed or enlarged the palace of his grandfather at Kouyunjik, and added to that at Shereef-Khan. Remains of an edifice belonging to his son, rudely constructed, and without the usual ornamental sculptures, were discovered in the south-east corner of the mound of Nimroud.

It is possible that all these palaces may have been built upon the sites of more ancient edifices, of which, however, no traces have hitherto been found. There can be little doubt that Nineveh was founded several centuries previous to the erection of the earliest buildings as yet uncovered. If any value is to be attached to the dynastic lists of Ctesias and other Greek writers, which are, however, rejected as entirely untrustworthy by the interpreters of the cuneiform inscriptions, the city must have existed nearly twenty-two centuries B.C.; and this conjecture is strengthened by its agreement with biblical chronology. The name of Nineveh occurs more than once on Egyptian monuments of Thothmes III., or fourteen centuries B.C. Kings who occupied the throne long previous to the first Sardanapalus, the builder of the north-west palace at Nimroud, are mentioned in the inscriptions; but although Nineveh appears to have been a flourishing city even under those monarchs, the capital of the empire, according to Sir Henry Rawlinson, was some 60 miles lower down the Tigris, on the western bank, and is marked by the ruins of Kalah-Sherghat, where monuments of a highly interesting character have been discovered. The first of these kings may have reigned about twelve centuries B.C., but there is reason to believe that events of Assyrian history are alluded to on monuments of a much earlier date. According to the inscriptions it would seem that Sennacherib was the first to move the seat of government to Nineveh, which he almost entirely rebuilt, the city having fallen into decay and ruin. But it must be observed, with reference to all conjectures founded upon the interpretation of the cuneiform characters, that our present knowledge of the ancient writing and language of Assyria is far too uncertain to admit of any positive conclusions. The dates of the earlier edifices at Nineveh depend entirely upon the correct rendering of the inscriptions. We know that the ruins of the north-west palace at Nimroud are the most ancient yet discovered, and the traditions still existing in the country point to them as such; but as yet we have no positive evidence to identify its founder with any monarch mentioned in history, or the date of whose reign can be established by any proof.¹ On the other hand, there is much concurrent evidence of a very remarkable character, besides the interpretation of the names on the monuments themselves, to enable us to assign the palaces of Khorsabad, and Kouyunjik to Sargon and Sennacherib. On monuments of the latter monarch have been discovered inscriptions of extraordinary interest, containing the name of Hezekiah, and a record of the invasion of Judea and siege of Lachish, mentioned in the book of Kings.

¹ On the black obelisk (now in the British Museum) raised by the son of the founder of the north-west palace, mention is believed to be made of Jehu, the son of Omri, "Yahua, the son of Kumri," and of Samaria as "Beth-Kumri," (the House of Omri); and on monuments from the same edifice, Benhadad, King of Damascus (1 Kings xx.) is supposed to be included in the list of kings who paid tribute to Assyria. In an inscription of a later monarch, ascertained to be the Scriptural Pul, "Menahem, King of Samaria, and Hiram, King of Tyre," are spoken of.

Nineveh.

Such being the ruins on or near the site of Nineveh, and their relative antiquity, it remains to be determined which represent the ancient city. It is evident that the space inclosed within the quadrangle opposite Mosul could not have contained a capital of such vast extent and importance as is assigned to Nineveh by the concurrent testimony of sacred and profane writers. The description in the book of Jonah is too vague and obscure to convey any definite idea of its size. Do the three days' journey imply the circuit of the city, its extreme length, or the time employed in traversing its principal streets? Are the "six score thousand persons who did not know their right hand from their left" intended to comprise a particular class, such as children; or is the expression used to mark the general ignorance of the whole population? In the one case, the city would have been of enormous extent, and would have contained about 600,000 inhabitants; in the other, it would have been of moderate size, with a population of 120,000. The dimensions assigned to Nineveh by the Greek geographers are more definite; and although in many respects undoubtedly fabulous, curiously confirm those given in the book of Jonah. Diodorus Siculus, who derived his information chiefly, it would appear, from Ctesias, states that the city formed a quadrangle 150 stadia by 90, the square being thus 480 stadia, or about 60 miles, corresponding to the three days' journey of Jonah. Strabo declares that Nineveh was larger than Babylon, the circuit of whose walls were, according to him, 385 stadia; and according to Herodotus 480. The inclosure of Kouyunjik being scarcely 9 miles in circuit, including even the outer ramparts, cannot be that described by Diodorus; but as an instance of the inaccuracy of Greek writers in giving such dimensions, or of errors that may have crept into the text of their works, we find this very quadrangle opposite Mosul stated by Xenophon, after actual personal observation, to be six parasangs, or about 18 miles in circuit, just double its actual extent.¹

To reconcile all conflicting statements, it has been conjectured that Kouyunjik, Khorsabad, Nimroud, and Karamles, with the numerous ruins in the intervening plain, may represent altogether the site of Nineveh. The careful surveys of Captain Felix Jones of the East India Company's navy (published by the East India Company), prove that these mounds occupy the four corners of a square, inclosing an area agreeing very nearly with that assigned to the city by Diodorus. It is assumed that each of these four groups was a fortified quarter of the city, a place of refuge and defence, including the palace of the king and his attendants, the temples and the dwelling-places of those attached to them, and the royal park or paradise. The space between them is assumed to have been occupied by the habitations of the people at large, scattered far and wide over the face of the country, and not collected together, as in a European city, by gardens and by cultivated fields. This is not inconsistent with Eastern habits. Ispahan and Damascus, with their suburbs, are cities of this kind. Within the precincts of Babylon, according to Diodorus Siculus and Quintus Curtius, corn could be raised sufficient for the sustenance of the whole population, in the event of a siege.

On the other hand, if the inscriptions be correctly deciphered, the inclosure opposite Mosul was alone called Nineveh; Khorsabad and other mounds around having distinct names. Nimroud (the *Larissa* of Xenophon) Sir H. Rawlinson would identify with Calah, mentioned in the 10th chapter of Genesis. But then no ruins, except Selmiah, which are not of sufficient extent or importance, would mark the site of Resen, "a great city between

Nineveh and Calah." He assumes that all the ruins described represent separate and distinct cities, which were, however, in the time of the prophet Jonah, known altogether by the common name of Nineveh. It is quite clear that, whatever may have been the extent of the city, there were no walls corresponding in extent with the description of Diodorus. If such ever existed, it is impossible that no traces of them should be found.

There are no remains to show the general plan of the city or of its principal quarters, the form of its streets, or the nature of the common dwelling-places of its inhabitants. It probably consisted, like most modern Eastern cities, of a few great edifices devoted to royal or sacred purposes, and constructed of rich and valuable materials; the abodes of the people being of the meanest and rudest description. Bricks made of clay, mixed with chopped straw, and simply dried in the sun, were generally used for building, as they still are in Assyria. Houses so built, when once abandoned, soon fell into complete decay; and their ruins, exposed to the winter rains and the summer's sun, soon crumbled to dust. A modern Arab village, when once deserted, disappears in a few years, leaving scarcely a trace behind. Masonry of sun-dried bricks, when properly protected, and when buried, as in the Assyrian mounds, defies the ravages of time. The walls of the palaces of Nineveh in this material are in many places still as perfect as when first raised.

The great public edifices have alone been sufficiently well preserved to furnish any idea of the style of architecture presented at Nineveh. Assyrian architecture appears to have originated on the banks of the Tigris and Euphrates. It owes its distinctive features to the fact of the first great public edifices of the race which devised it having been erected upon the plains of Assyria and Babylonia. In order to raise the building, for the sake of dignity or defence, high above the surrounding country, it was necessary to form an artificial elevation, and those enormous platforms or mounds were constructed which form one of the chief characteristics of Assyrian and Babylonian ruins. This substructure was either of solid masonry of sun-dried bricks, or simply of earth and rubbish heaped up. In the bas-reliefs from Kouyunjik is represented the process of building it. Long lines of workmen, many of them prisoners or slaves, chained together and in fetters, are seen emptying baskets filled with earth and stones on the accumulating heap. The substructure was raised about 40 or 50 feet above the level of the plain, and was generally faced with masonry or stone. Broad flights of steps led up to the summit. The public edifice or palace was constructed principally of sun-dried bricks, but parts of the building required more solid and more costly materials. To supply the first, the kiln-burnt bricks were used; for ornament, the Ninevites employed a coarse grayish alabaster found in abundance in the immediate vicinity of their city. A remarkable feature in these buildings was the immense thickness of the walls, rarely less than 10 feet, generally about 15 feet. They were built of sun-dried bricks, and panelled with upright sculptured alabaster slabs, from 8 to 10 feet high, 3 to 4 feet broad, and about 18 inches thick, placed close to one another, but not united by any mortar or cement. Above these slabs the wall was either faced with kiln-burnt bricks, plain or coated with enamel, forming elegant designs and patterns of the most brilliant colours, or plastered and painted. Cedar and other precious woods, gilding, ivory, and bronze, were also used to decorate the sides of the chambers. These materials appear to be mentioned in the inscriptions as having been brought from afar; cedar-wood, for instance, from Mount Lebanon. The ceil-

Nineveh.

¹ The length of Xenophon's parasang may be determined by reference to the distances assigned to the marches of the Ten Thousand in their retreat.

Nineveh. ings of the rooms were also probably of cedar. Large quantities of this precious wood were found in the ruins of Nimroud. There is reason to believe that many of the chambers were vaulted. Discoveries in the ruins prove that the Assyrians were well acquainted with the principle of the arch, and employed it in forming these entrances. The principal doorways, and generally all those leading into the great halls or courts, were flanked by those well-known emblematic figures, now characteristic of Assyrian architecture, uniting the body of a lion or a bull with the head of a man and the wings of an eagle. These were usually of gigantic proportions, and on these were generally inscribed the annals of the reign of the king who caused them to be erected.

The alabaster slabs placed against the walls were sculptured in bas-relief, or had an inscription carved upon them. The sculptures were of two kinds—either figures of priests or divinities of colossal size, or subjects representing battles, sieges, hunting scenes, sacrifices, &c. In the latter case, the slab was divided into two parts by an inscription running across in a horizontal band, and containing a description of the work portrayed above or beneath. Remains of colour upon the bas-reliefs prove that they were originally painted. The pavement of the chambers consisted of alabaster slabs, either carved with rich and elegant pictures, or covered with inscriptions, or more usually of large square kiln-burnt bricks. On the back of almost every slab or stone used in the building was carved the name of the king who founded it, together with a short inscription containing his titles, the names of the principal gods, and the countries he ruled over. Upon the kiln-burnt bricks also was generally stamped or inscribed the name of the king. The interior of these magnificent edifices was adorned with statues of the gods and of the king, and with obelisks and stelæ of marble and other materials covered with bas-reliefs and inscriptions recording the conquest and other remarkable events of the reigns of Assyrian monarchs. Several of these monuments discovered in the ruins are now in the British Museum.

These vast edifices were probably at the same time the palace and the temple, the residence of him who was both the high priest and the political chief of the nation. These offices were at one time similarly united in Egypt, and the palace-temple was the dwelling-place of the king. Parts of the building may have been specially set apart for worship and dedicated to a particular god; but no detached temple, as in ancient Greece, has been as yet found on the site of Nineveh. The inscriptions, however, appear to mention the fact of temples of extraordinary magnificence, adorned with silver and gold, having been raised in different parts of the empire. The palace was also the house of records of the nation; on its walls were pictured and described its triumphs, and the prowess of its monarch in war and in the chase.

The palaces of Nineveh seem to have been constructed upon one general plan, and consisted of a number of chambers of various sizes grouped round large central halls, which were probably open to the sky, and resembled the courts of modern Persian houses. No columns of any kind, nor pedestals for pillars of wood for supporting a roof, have been discovered. Pillars of wood brought from distant countries appear to be mentioned in the inscriptions, and columns are frequently represented in the bas-reliefs. No traces of windows have been found in the walls; consequently, it may be presumed that the rooms were either lighted from above or through the doors only. The latter may have been the case, as in modern houses at Baghdad and Mosul, in which, for the sake of coolness, the apartments are kept as dark as possible. From the immense heap of bricks, earth, and rubbish covering every part of the ruins, and filling every

chamber, frequently rising as much as 15 or 20 feet above the level of the sculptured slabs, as well as from the representations of buildings seen in the bas-reliefs, it is probable that these palaces consisted of more than one storey, and that the upper part having fallen in, completely buried the lower. The admirable preservation of the greater part of the sculptures, although executed in a very soft material, which would have perished from even short exposure, proves that such must have been the case, and that the entire destruction of the buildings must have been very sudden.

No remains of the outer walls of an Assyrian palace, hitherto discovered, are sufficient to furnish an accurate idea of the exterior architecture of Nineveh. Only the lower part of a façade at Kouyunjik has yet been excavated. It consists of three grand entrances formed by groups of colossal winged bulls and human figures, some flanking the doorways, others placed back to back, and facing outwards. From what still remains, and by comparison with ancient buildings in other parts of the East, principally in Persia, Mr Fergusson (*Palaces of Nineveh and Persepolis Restored*) has with great ingenuity endeavoured to restore a Ninevite palace. The discoveries at Kouyunjik of bas-reliefs supposed to represent an Assyrian edifice go far to verify his conjectures. There is nearly the same arrangement of columns in an upper storey resting upon a solid basement. The capitals are ornamented with volutes resembling those of the Ionic order, and they rest upon the backs of winged bulls and sphinxes. The Persians appear to have derived both their religion and their architecture from the Assyrians. The latter was somewhat modified by locality, and by the vicinity of quarries of fine building-stone; but the palaces of Xerxes and Darius at Persepolis were erected upon nearly the same plan, and were adorned with nearly the same ornaments and the same typical figures, as those at Nineveh. Being built chiefly of stone, they have defied for a longer period, although exposed to the air, the ravages of time. One of the most remarkable facts connected with the discovery of the ruins of the palaces of Nineveh is, the proof which they afford that the Greeks derived their Ionic order of architecture from Assyria. It reached them through Asia Minor and Ionia. Not only was the Ionic volute the ordinary termination to an Assyrian column, but the usual ornaments found on Ionic monuments in Greece are for the most part purely Assyrian. According to the interpretation of the inscriptions, the kings of Assyria shortly before the fall of the empire employed Greek and Phœnician artists in decorating their palaces, and records have been found of the names of the kings who sent them and the cities from whence they came.

Another important result of the discoveries at Nineveh is, that they enable us to understand the architectural descriptions contained in the Bible, and especially those relating to the palaces and temples erected by Solomon, to which, both in the general plan, the materials employed, and the style of the ornaments, they appear to have borne a very close resemblance. The Jewish edifices were, however, far inferior in size to those of Assyria.

According to a tradition preserved by Greek authors, Nineveh was finally captured by the Persians and Babylonians through a breach in its walls caused by a sudden overflow of the waters of the Tigris. There are no indications of this event either in the ruins of Kouyunjik or of Nimroud. All the edifices hitherto discovered, except the north-west palace, attributed to Sardanapalus, show undoubted marks of having been destroyed by fire, and many conclude that the city was at last overwhelmed, never to rise again, by one mighty conflagration. (A. H. L.)

NING-PO, an important city of China, one of the five seaports open to foreign trade, and the principal emporium in the province of Che-Keang, stands in a fine plain on the

Ning-po.

Ninian
||
Ninians, St.

left bank of the Takia, Lat. 29. 51. N.; Long. 121. 32. E. It is surrounded by walls, having a circumference of 5 miles, a height of 25 feet, a breadth of 22 feet at the base and 15 at the summit; and is entered by five gates. The walls are in a state of considerable dilapidation, and there are large suburbs on the outside. Although considered by the Chinese as one of the finest cities in the empire, Ning-po does not strike Europeans as at all remarkable for its elegance; the streets being very narrow and dirty, and the houses, built for the most part of brick, rarely exceeding one storey in height. It is intersected by several canals, and the river is crossed by a floating bridge. Among the principal buildings are a hexagonal brick tower of seven storeys, 160 feet high, and said to be upwards of 1000 years old; numerous pagodas and public offices; as well as the temple of *Ma Tsupu*. Near the margin of the river there are numerous shops and storehouses, which excel in wealth and splendour those of Canton; and near the city gates there are many eating-houses and tea-shops. A missionary hospital, which was founded here in 1843, is of great public utility, and is used not only by the poorer classes, for whom it was specially intended, but by all ranks of society. Manufactures of silk are carried on here, as at Canton; cotton stuffs, carpets, furniture, &c., are also produced; and in the vicinity are large salt-works. The building of junks is also carried on to a considerable extent. The trade of the place is very considerable, as it is the principal port intermediate between the northern and southern provinces; and owing to the superior speed and safety of British vessels, the coasting seems to be rapidly passing out of the hands of the Chinese. The number of British vessels that entered and cleared here in 1856 was 206; tonnage, 26,004. British goods are only imported to a small extent; but large quantities of the produce of Singapore and the Straits of Malacca find a market here. Among the exports to Great Britain in 1856 was green tea to the value of L.4328; and the principal other articles of export are raw and manufactured goods of native produce, for the use of the Chinese on the coasts and in the British colonies. The trade of the port is on the whole in a flourishing and increasing condition. Pop. estimated at between 200,000 and 300,000.

NINIAN, or NINYAS, commonly called *St Ninian*, and sometimes *St Ringan*, a distinguished bishop among the ancient Britons, and said to be the first who carried the light of Christianity into Scotland, seems to have been a Briton of noble birth and excellent genius. After receiving a tolerable education at home, he visited Rome in A.D. 370, where he spent several years in study. On his return to Britain he engaged with great zeal and success in preaching the gospel in the most uncultivated parts of the island. He chose the modern Whitehorn in Wigtownshire as the centre of his operations (called by Ptolemy, ii. 3, *Λουκοπιβία*; and by the Romans, who had a station there, *Candida Casa*), then one of the two towns of the Novantæ (the *Noovantæ* of Ptolemy), who inhabited *Gallovidia* (Galloway). We learn from Bede (*Hist. Eccles.*, lib. iii.), that Ninian built a fine church there about A.D. 400, which he dedicated to St Martin; and owing to his great success as a Christian missionary was afterwards made bishop of Whitehorn. This place was the centre of Christian light in Scotland for more than a hundred years before the arrival of Columba. Some of the ruins of St Ninian's church are still shown at Whitehorn; and various localities in Scotland still bear traces of the name and the reputation of this zealous missionary.

NINIAN'S, ST, a village and parish of Scotland, in the county of Stirling, about 1 mile S. of the town of Stirling. It consists of one main street of old whitewashed houses; and has a parish, a Free, and a United Presbyterian church; and several schools. Malt, whisky, leather, carpets, tartans,

nails, &c., are manufactured here. Pop. of the parish (1851) 9851. Ninove
||
Nipissing.

NINOVE, a town of Belgium, in the province of East Flanders, on the left bank of the Dendre, 20 miles S.E. of Ghent. It contains several churches and schools, a town-hall, and an hospital. There are breweries, dyeworks, bleachfields, brick-kilns, and manufactories of earthenware, leather, soap, tobacco, vinegar, thread, linen and woollen fabrics, &c. Some trade is carried on in wool, grain, cattle, and manufactured articles. Pop. 4718.

NIOBE, the daughter of Tantalus, King of Lydia. The incidents in her life are related differently by different authors; but the following is the simple legend given by Homer:—She was married to Amphion, King of Thebes, and bore to her husband six sons and six daughters. Proud of the number of her children, she began to assert a scornful superiority over Latona, who was a less happy wife. Hereupon Apollo and Diana, enraged at the insult cast upon their mother, bent their bows, and slew the sons and daughters of the doting Niobe. The childless queen, in her distracted sorrow, found her way eastward to her father's kingdom. As she stood one day on Mount Sipylus, in the motionless attitude of mute despair, she was changed by the commiserating Jupiter into stone. There for many ages afterwards the simple-minded believer of legends could still detect in the rough outline of a crag the weeping figure of the unhappy Niobe. This story was the subject of several ancient sculptures. One of these, a group of fourteen statues, representing the mother in the midst of her dying children, was dug up at Rome at some date before 1583, and was conveyed to Florence in 1775. It now stands in the Uffizi gallery of the latter city, exciting by its grandeur the admiration of connoisseurs. (See ARTS, *Fine*.) Various conjectures have been made regarding the authorship and the original position of these statues. Winckelmann supposed that they were the work of Scopas; and the English architect Cockerell has shown that they were probably arranged on the tympanum of a temple.

NIORT, a town of France, capital of the department of Deux-Sèvres, stands in the midst of a rich and beautiful region, on the slopes of two hills, separated by the Sèvre-Niortaise, 79 miles S.E. of Nantes, and 225 S.W. of Paris. It was formerly very meanly built; but has recently been much improved, and has now many handsome streets and two fine public squares. There are two churches, one of which is an ancient Gothic building with a lofty spire; a town-hall, formerly the palace of Eleanor of Guienne, queen of Henry II. of England; an old castle now used as a prison, in which Madame de Maintenon was born; a prefecture, a theatre, public library, baths, cavalry barracks, civil and military hospitals, &c. Niort is the seat of courts of primary jurisdiction and of commerce, of a council of *prud'hommes*, an agricultural society, and a commercial college. The principal manufactures are leather and gloves, especially of doeskin, of which not less than 30,000 dozen are annually made. Shoes, woollen and cotton yarn, saddles, paper, saltpetre, articles of wood and horn, &c., are also produced here. The commerce of the place is considerable in wine, corn, flour, wool, timber, manufactured goods, &c. The Sèvre is navigable as far as Niort. Pop. (1856) 18,136.

NIPHON. See JAPAN.

NIPISSING, LAKE, a lake of Upper Canada, lying midway between the Ottawa or Grand River and Georgian Bay, an inlet of Lake Huron. Its form is irregular; its length is about 48 miles, its greatest breadth 25, and its altitude 750 feet above the sea. Its principal affluent is the Sturgeon River from the N., which connects it with other lakes; and it discharges its waters by the French River into Lake Huron. The lake contains several islands, occupied by Indians; and abounds in large flocks of geese.

Nisan NISAN, the first month of the Hebrew civil year. (See ABIB.)

NISHAPOOR, a town of Persia, province of Khorassan, the capital of a district of its own name, stands in a beautiful valley, 46 miles W. by S. of Meshed. It is meanly built, for the most part of mud, and many of the houses are in ruins. A wall and ditch, with a circumference of about 4000 paces, surround the town, in which the only public buildings are an unsightly mosque and a pretty large and well-filled bazaar. About 40 miles W.N.W. of Nishapoor there are eight or nine mines of very fine turquoises, from which our supply of these stones is chiefly derived; but most of them are very ill worked, and some have been entirely abandoned; so that their produce it much less than it might be under proper management. The town is said to be very ancient, and to have existed in the time of Alexander the Great, by whom it was destroyed. Under the Seljuk dynasty it was one of the four royal cities of Khorassan. In 1269 it was sacked by the Tartars; again by Jhengiz-khan; and, in 1749, by Nadir Shah; from which last calamity it has never recovered. Pop. estimated at 8000.

NISI PRIUS, a legal phrase derived from an ancient writ in which the words occur. Previously to the statute of Westminster 2, trials by assizes or juries could only take place where the king happened to reside, or before the justices on their septennial circuit through the English counties; but by 18th Edw. I., cap. 30, the judges were directed to hold certain assizes in every county not oftener than three times in every year. The statute required that the day and place in the county in which a case was to be tried should be specified in the writ which assembled the jury. Instead, accordingly, of the old writ, commanding the sheriff to bring the jury to Westminster to try the cause, a *nisi prius* clause was added to the writ as follows:—"We command you, that you cause to come before our justices at Westminster, on the morrow of All Souls, twelve lawful men, who, &c., unless before (*nisi prius*) that day A. B. and C. D., our justices assigned for that purpose, shall come to your county to take the assizes there." The day of summons to Westminster is always arranged to be later than the day for taking the county assize, and hence the cause is always tried before the date at which the sheriff is commanded to return the jury to Westminster. In time, the phrase *nisi prius* came to be applied to a large class of judicial business transacted at the several assizes throughout the country before judges of the superior courts. Judges of assize are called judges of *nisi prius*; they are said to be sitting at *nisi prius*, when sitting alone to try causes, and the law by which their decisions are regulated is called the law of *nisi prius*.

NISMES, or NÎMES (anc. *Nemausus*), a town of France, capital of the department of Gard, stands in a wide and fertile plain, between the Rivers Gard on the N., and Vistre on the S., 23 miles W.S.W. of Avignon, 30 N.E. of Montpellier, and 62 N.W. of Marseilles. The older part of the town is surrounded by boulevards, on the site of the fortifications by which it was once defended; and contains narrow and irregular streets lined with old and ill-built houses. The boulevards form fine broad streets, with handsome houses, and are planted with trees; while the outer parts of the town, which comprise about three-fourths of its whole extent, have wide and regular streets, and handsome modern edifices. The line of the Roman walls of Nismes may still be traced; and some parts of them, and two of the gates, are in good preservation. The principal public buildings of the town are those of Roman origin. Of these the largest is the amphitheatre, an oval structure, which now stands, since the adjoining buildings have been cleared away, in the middle of a large open space; it is 437 feet long, 332 broad, and 70 high. The exterior

is very well preserved, though the building was used as a fortress in the middle ages. It has two storeys, each consisting of sixty arches. Within these arches, on each storey, a corridor runs entirely round the building; that in the upper storey being smaller than the lower. Access is gained to the interior by four entrances facing the four points of the compass; and from these wedge-shaped passages lead to the centre, and stairs to the upper seats. On the exterior are also to be observed the holes in which the poles were inserted for supporting the awning which shaded the spectators from the heat of the sun. The interior is not so well preserved; but some of the ancient seats, of which there were thirty-two rows, are still to be seen. It is believed that this amphitheatre could contain upwards of 17,000 spectators. Parts of the interior have been restored, but rather clumsily, by a modern architect; and it is still used by the people of Nismes for bull-baiting and other favourite exhibitions. The date of the building is unknown. Antoninus Pius, Titus, and Adrian, have been each conjectured to have been its founder. Another fine building of Roman construction is a Corinthian temple, commonly called the *Maison Carrée*, which is adorned with thirty elegant Corinthian columns. It seems to have originally stood in the market-place of Nemausus, which was inclosed by a colonnade. It has been employed at different times as a heathen temple, a Christian church, a town-hall, a stable, a burial-place, a court-house, a corn warehouse, and a museum; in the last of which capacities it still remains, and contains some antique remains and pictures. A temple of Diana, or, according to some, of the Nymphs; a reservoir, forming the termination of an aqueduct; and a curious octagonal tower, called *La Tourmagne*, whose origin is unknown,—are the chief other ancient buildings in Nismes. Besides these, the town has a cathedral, built in the eleventh century, but considerably altered in subsequent times; several elegant churches; an episcopal palace and seminary; a college, public library, court of justice, barracks, hospital, theatre, &c. Nismes is also the seat of an appeal court for the departments of Gard, Lozère, and Vaucluse; of courts of primary resort and of commerce; a school of design; agricultural and medical societies, &c. As a manufacturing town it holds a high rank; and in the produce of silk it is among the most important places in France. There are several large establishments for dyeing and for printing silk stuffs; but the weaving, which employs from 7000 to 8000 looms in Nismes, is principally carried on by the workmen at their own houses, and not in factories. The silks of Nismes are generally imitations of those of Lyons, and of inferior quality; they are principally used by the lower classes. Tanneries, distilleries, vinegar-works, and potteries, are among the chief manufactories of the place; and in addition to the articles already mentioned, cotton handkerchiefs, hosiery, velvet, chintzes, &c., are extensively produced. An active trade is carried on, especially in raw silk, for which it is the principal emporium in the south of France; and in wine, vinegar, spices, drugs, &c. The importance of Nismes has been recently increased by the construction of railways diverging from this town to Montpellier, Alais, Avignon, Arles, and Marseilles. (Its ancient history is given under NEMAUSUS.) After the fall of the Roman empire it fell into the hands of the Visigoths, who were dispossessed in the beginning of the eighth century by the Moors. The latter were expelled from Nismes by Charles Martel, on which occasion the amphitheatre was partially destroyed by fire, and the town much injured. At the Reformation the greater part of the inhabitants embraced the Protestant religion, and were in consequence subjected to great persecution and cruelty. About one-third of the population are still Protestants, and these form the most wealthy classes in the town. The greatest religious animosity is still kept up between the two sects; and

Nismes.

Nissa
||
Nivelles.

in 1815 a renewed outburst of intolerance on the part of the Roman Catholics took place. In more peaceful times the mutual aversion of the two parties is shown by the way in which they keep aloof from one another, even frequenting different places of amusement. Nismes was the birth-place of Nicot, who introduced tobacco into France; and of Guizot the historian. Pop. (1856) 49,291.

NISSA, or NIŠCH, a town of European Turkey, in the province of Servia, stands in a fertile and well-cultivated plain, between two branches of the Balkan Mountains, 60 miles S.S.W. of Widdin, and 130 S.E. of Belgrade. It is separated into two parts by the River Nissava, an affluent of the Morava. The division on the right side, occupied by Turks, is surrounded by good fortifications and a dry ditch; while on the other side is a bazaar, defended by a trench and palisade; and beyond this is the unprotected Christian quarter. The fortifications are mounted with numerous large guns; and Nissa commands the communication between the provinces of Servia, Bulgaria, and Roumelia. The principal building is the palace of the pasha. This place was anciently called *Naissus*; and is remarkable as the birth-place of the Emperor Constantine. It was taken by Amurath II. in 1389, and again by the Austrians in 1737. Pop. 10,000.

NITH, a river of Scotland, rises on the confines of Ayrshire, Kirkcudbrightshire, and Dumfriesshire, flows S.E. through Dumfriesshire, and falls into the Solway Firth after a course of 45 miles. The principal towns on its banks are New Cumnock and Dumfries, the latter about 8 miles from its mouth. The Nith has salmon fisheries of considerable value. It has been rendered a classic stream by the poetry of Burns, who resided for some time at the farm of Ellisland, near Dumfries.

NITHARD, an old French historian, was the son of the famous Abbot Angilbert, and of Bertha, the daughter of Charlemagne, and was born at some date before 790. Succeeding his father as duke or count of the maritime coast, he seems to have risen to an influential position at court. After the death of his uncle Louis Le Débonnaire in 840, his services were employed to effect a reconciliation between the three sons of that monarch; but he was unsuccessful in his negotiations, and it was soon his duty to record the war which broke out between the brother princes. His death took place in 858 or 859, in consequence of a wound which he received in repelling an invasion of the Normans. The history of Nithard is inserted in Duchesne's *Historia Francorum Scriptores*, in 5 vols. fol., Paris, 1636-41-49. A French translation has recently appeared in the *Collections des Mémoires Relatifs à l'Histoire de France*, of Guizot.

NITI, a celebrated pass over the Himalaya Mountains, so called from a village of the same name in the vicinity, in the British district of Kumaon, in the North-West Provinces. The ascent from the southern side is for a great part of the way very steep, over rocks of blue limestone; and on the other side it leads to the valley of the Sutlej, which is here 14,924 feet above the sea-level. The height of the crest of the pass is 16,814 feet above the sea. At this great elevation the rarity of the air has been felt by travellers to produce the most painful effects; and even of those natives who train themselves for the purpose of crossing the mountains, some can never bring themselves to endure it. The pass remains open from the end of June till the middle of October; and during that time the most of the trade between Hindustan and Chinese Tartary is carried on by it; the merchandise being conveyed on the backs of yaks, goats, and sheep.

NIVELLES, a town of Belgium, province of South Brabant, stands on the Thienne, 17 miles S. of Brussels. It is not very well built, but has two large squares and a fine public walk. There are 3 churches; one of which, that of St

Gertrude, is a fine edifice in the Romanesque style, built in 1048. It contains two finely carved pulpits, one of wood and the other of marble; and has two towers, the lower of which contains a chime of bells, on which the hours are struck by a colossal figure called *Jean de Nivelles*. The crypt is considered one of the finest in Belgium, and is much resorted to by pilgrims. Nivelles has also a convent, a college, normal school, academy of design and architecture, hospital, court of primary jurisdiction, &c. Manufactures of linen, woollen, and cotton stuffs, hats, lace, paper, oil, tobacco, and other articles are carried on here; and there is a considerable trade in corn, cattle, and swine. The town owes its origin to an abbey founded in 645 by St Gertrude, some cloisters of which still remain. It is said to have been much more populous in the sixteenth century. Pop. 8499.

NIVERNAIS, an old province of France, which comprises the present department of Nièvre and part of that of Cher.

NIXDORF, a town of Bohemia, in the circle of Leitmeritz, stands near the borders of Saxony, 34 miles N.E. of Leitmeritz. Manufactures of linen, hosiery, cutlery, and hardware are carried on; and the latter articles are exported to all parts of Germany. In the neighbourhood are mineral springs, over which baths have been erected. Pop. 5090.

NIZAM'S DOMINIONS. See HYDERABAD.

NIZZA MONFERRATO, a town in the kingdom of Sardinia, in the division of Alessandria, stands at the confluence of the Belbo and Nizza, 16 miles S.W. of Alessandria. It has a silk-mill, and some trade in wine. Pop. 4376.

NOAH. See DELUGE.

NOBILITY, in the technical acceptance of the word, means generally that quality or dignity which raises a man above the rank of a commoner. Among the Romans, the *nobiles* or "known" men, were so called by way of distinction from the *ignobiles*, or vulgar, who were "not known." Originally the Roman patricians were the nobles, but B.C. 336 the plebeians obtained the right to rise to high offices in the state, and subsequently the descendants of plebeians who had filled curule magistracies inherited the *jus imaginum*, or right of holding the images of their ancestors—a sort of coat of arms; and were accordingly ranked with the *nobiles*, and bore the dignity of *nobilitas*. He that had only his own image was a *novus homo*, and he that had neither his ancestors' nor his own was an *ignobilis*.

"The distinction of rank and honours," says Blackstone, "is necessary in every well-governed state, in order to reward such as are eminent for their services to the public, in a manner the most desirable to individuals, and yet without burden to the community; exciting thereby an ambitious yet laudable ardour, and generous emulation in others. And emulation, or virtuous ambition, is a spring of action which, however dangerous or invidious in a mere republic or under a despotic sway, will certainly be attended with good effects under a free monarchy, where, without destroying its existence, its excesses may be continually restrained by that superior power from which all honour is derived. Such a spirit, when nationally diffused, gives life and vigour to the community; it sets all the wheels of government in motion, which, under a wise regulator, may be directed to any beneficial purpose; and thereby every individual may be made subservient to the public good, while he principally means to promote his own particular views. A body of nobility is also more peculiarly necessary in our mixed and compounded constitution, in order to support the rights of both the crown and the people, by forming a barrier to withstand the encroachments of both. It creates and preserves that gradual scale of dignity which proceeds from the peasant to the prince; rising like a pyramid from a broad foundation, and diminishing to a point,

Nivernais
||
Nobility.

Nobility. as it rises. It is this ascending and contracting proportion that adds stability to any government; for when the departure is sudden from one extreme to another, we may pronounce that state to be precarious."

The origin of nobility is a subject involved in obscurity. In the infancy of almost every nation we meet with a hereditary nobility of some sort. It originally had a reference doubtless to superior merit; and in early times is found most frequently attaching to the warrior or the priest. An interesting passage bearing on the origin of hereditary nobility occurs in the *Franca Gallia* of Francis Hotman, written in 1574. He says, "We must not omit making mention of the cunning device made use of by Hugh Capet for establishing himself in his new dominions (as king of France A.D. 987). For whereas all the magistracies and honours of the kingdom, such as dukedoms, earldoms, &c., had been hitherto, from ancient times, conferred upon select and deserving persons in the general conventions of the people, and were held only during good behaviour, whereof (as lawyers express it) they were but beneficiaries, Hugh Capet, in order to secure to himself the affections of the great men, was the first that made those honours perpetual, which were formerly but temporary, and ordained that such as obtained them should have an hereditary right in them, and might leave them to their children. Of this see Franciscus Conanus the civilian, *Comment. i.*, ch. 9." (Burke's *Peerage*).

Sir James Lawrence, who, in his *Nobility of the British Gentry*, maintains that gentility is superior to nobility (*fit nobilis, nascitur generosus*), holds that a coat of arms is the criterion of nobility. (See *HERALDRY*.) He says (p. 3), "Any individual who distinguishes himself may be said to ennoble himself. A prince, judging an individual worthy of notice, gave him letters patent of nobility. In these letters were blazoned the arms that were to distinguish the shield. By this shield he was to be known, or *nobilis*. A plebeian had no blazonry on his shield, because he was *ignobilis*, or unworthy of notice. In an age when a warrior was cased in armour from head to foot, he could only be known by his shield. The plebeian who had no pretensions to be known was *chypeo ignobilis albd*. Hence arms are the criterion of nobility. Every nobleman must have a shield of arms. Whoever has a shield of arms is a nobleman. In every country in Europe, without exception, a grant of arms or letters of nobility is conferred on all the descendants. In the northern countries—Germany, Hungary, Russia, Sweden, Denmark—the titles also of baron or count descend to all the male posterity, and to all the unmarried females of the family; but in the southern countries—France, Spain, Portugal, and Great Britain—the titles of duke, marquess, count, viscount, or baron, descend only according to the rules of primogeniture."

In Great Britain nobility extends to the five ranks of duke, marquess, earl, viscount, and baron. (See under each.) The right of peerage seems to have been originally territorial; that is, annexed to lands, honours, castles, manors, and the like, the proprietors and possessors of which were, in right of those estates, allowed to be peers of the realm, and were summoned to Parliament to do suit and service to their sovereign; and, when the land was alienated, the dignity passed along with it as an appendage. Thus in England the bishops still sit in the House of Lords, in right of succession to certain ancient baronies annexed, or supposed to be annexed, to their episcopal lands; and thus (11 Henry VI.) the possession of the castle of Arundel was adjudged to confer an earldom on its possessor. But afterwards, when alienations became frequent, the dignity of the peerage was confined to the lineage of the party ennobled, and, instead of territorial, became personal. Actual proof of a tenure by barony became no longer necessary to constitute a lord of parliament; but the record of the writ of

summons to him or his ancestors was admitted as a sufficient evidence of the tenure. Peers of Great Britain are now created either by writ or by patent; for those who claim by prescription must suppose either a writ or patent to have been issued or granted to their ancestors, though by length of time it has been lost. The first of these summonses on record was made in the forty-ninth year of Henry III.; and the first instance of barons made by letters patent dates from the reign of Richard II. The creation by writ or the king's letter is a summons to attend the House of Peers, by the style and title of that barony which the king is pleased to confer: that by patent is a royal grant to a subject of any dignity and degree of peerage. The creation by writ is the more ancient way; but a man is not ennobled thereby unless he actually take his seat in the House of Lords; and some are of opinion that there must be at least two writs of summons, and a sitting in two distinct Parliaments, to establish a hereditary barony; and therefore the most usual, because the surest way is to grant the dignity by patent, which endures to a man and his heirs according to the limitation thereof, although he himself should never make use of it. Yet it is customary to call up the eldest son of a peer to the House of Lords by writ of summons, in the name of his father's barony, because in that case there is no danger of his children losing the nobility in the event of his never taking his seat, seeing they will succeed to their grandfather. Creation by writ has also one advantage over that by patent. A person created by writ holds the dignity to himself and his heirs, without any words to that purport in the writ; but in letters patent there must be words to direct the inheritance, otherwise the dignity endures only to the grantee for life.

The nobility of England are, as elsewhere, a privileged order. In criminal cases a nobleman must be tried by his peers—a privilege, indeed, secured to all by Magna Charta (c. 29). It is said that the privileges of nobility do not extend to bishops, who, though they are lords of Parliament, and sit there by virtue of the baronies which they hold *jure ecclesiæ*, yet are not ennobled in blood, and consequently not peers with the nobility. As to peeresses, no provision was made for their trial when accused of treason or felony till after Eleanor, Duchess of Gloucester, wife to the Lord Protector, had been accused of treason, and found guilty of witchcraft, in an ecclesiastical synod, through the intrigues of Cardinal Beaufort. This very extraordinary trial gave occasion to a special statute (20 Hen. II., c. 9) which enacted that peeresses, either in their own right or by marriage, should be tried before the same judicators as peers of the realm. If a woman, noble in her own right, marries a commoner, she still remains noble, and must be tried by her peers; but if she be only noble by marriage, then by a second marriage with a commoner she loses her dignity; for as by marriage it is gained, so by marriage it is also lost. Yet if a duchess-dowager marries a baron, she continues a duchess still; for all the nobility are *pares*, and therefore it is no degradation. A peer, or peeress, either in her own right or by marriage, cannot be arrested in civil cases; and they have likewise many peculiar privileges annexed to their peerage in the course of judicial proceedings. A peer sitting in judgment gives not his verdict upon oath, like an ordinary jurymen, but upon his honour; he answers also to bills in chancery upon his honour, and not upon his oath; but when he is examined as a witness either in civil or criminal cases, he must be sworn; for the respect which the law shows to the honour of a peer does not extend so far as to overturn a settled maxim, that *in judicio non creditur nisi juratis*. The honour of peers is, however, so highly tendered by the law, that it is much more penal to spread false reports concerning them, and certain other great officers of the realm, than concerning other men; scandal against them being called by the peculiar name of *scandalum mag-*

Pagani
||
Noci.

natum, and subjected to peculiar punishment by different ancient statutes. In point of fact, however, their immunities have relation more to dignity than power. In their legislative capacity, the peers of England form an estate of the realm intermediate between the crown and the commons. In their judicial capacity they constitute the supreme court of justice, from whose judgment there is no further appeal. While bearing the minor crown, they wield no minor sceptre of personal power. They possess no regal jurisdiction, nor any sovereign seignior. No peer can invade with impunity the rights of a commoner, nor exercise any peculiar authority not open also to the commoner. A patent of English nobility, however, confers not only a title, but also a certain amount of political power and privilege. Yet there may be nobility without political privileges, as in the case of Scotch and Irish peers, who are not peers of the realm. There are also members of the House of Lords who are not peers of the realm, as in the case of the representative peers of Ireland and Scotland, and the bishops and archbishops of England and Ireland. The peerages of Great Britain and Ireland enjoy the same privileges in all other respects, however, except those depending upon sitting in the House of Lords (39 and 40 Geo. III. cap. 67). Peers of the realm are entitled to sit there either by hereditary claim, or from being elected by their own peers; whereas the rest of the nobility in the House of Lords are nominated by the crown to places which entitle them to a seat for life, or for certain fixed periods. New additions are constantly being made to the English peerage. The persons selected for this honour are drawn chiefly from the following classes:—Peers of Scotland and Ireland; members of families already among the nobility; distinguished lawyers, and naval and military commanders; persons eminent in political life; persons of extensive landed property, and some who have acquired great wealth and attained to social importance in commerce. Hitherto distinction in science and literature has been rewarded by no higher dignity in England than that of a baronet, which does not confer nobility; but this custom was broken through in 1857, in the case of Lord Macaulay, who was elevated to the rank of nobility as a reward for distinguished literary merit.

A peer cannot lose his nobility except by death or attainder, although there was an instance, in the reign of Edward IV., of the degradation of George Neville, Duke of Bedford, by act of Parliament, on account of his poverty, which rendered him unable to support his dignity. But this is a singular instance; and while it serves to show the power of Parliament, proves how tender that august assembly has always been in exerting so high a function.

In France the titles and armorial bearings of the nobility were abolished by order of the National Assembly, June 18, 1790, and the records of the French nobility, in 600 vols., were burnt two years afterwards. Napoleon created a new nobility in 1808, but the hereditary peerage was abolished in 1831.

NOCERA DEI PAGANI, a town of Naples, province of Principato Citra, at the foot of a hill occupied by the ancient citadel, in the middle of a series of isolated heights, 21 miles E.S.E. of Naples. It consists of straggling groups of houses, with gardens and trees between; and has several churches, a convent, a clerical seminary and other schools, and good cavalry barracks. Manufactures of linen and other stuffs are carried on. Nocera occupies the site of the ancient Nuceria, which was destroyed by Hannibal in his invasion of Italy. It is supposed to have received its modern epithet from a colony of 20,000 Saracens, who were settled here in the 13th century by the Emperor Frederick II., in opposition to the court of Rome and the Guelph faction. Pop. 6800.

NOCI, a town of Naples, province of Bari, 28 miles S.E. of the town of that name. It has a large hospital; and some trade in corn, wine, oil, and silk. Pop. 8000.

NODES, the two points where the orbit of a planet or comet intersects the ecliptic, or where the orbit of a satellite intersects the orbit of its primary. (See ASTRONOMY.)

NODIER, CHARLES, a distinguished French littérateur, was born at Besançon, April 29, 1780. From his father, who was mayor of his native town during the first years of the Revolution, he received an excellent classical training. While still a mere lad, he gave earnest of his future literary eminence by composing dramas and lyrics on classical themes, which were much admired by competent judges in the circle of his friends. Encouraged by their praises, he began to point his thoughts and studies to a definite aim, and in 1798 published his *Dictionnaire des Onomatopées*. This work, which displayed research and critical power remarkable in so young a man, was, by the advice of Fourcroy, adopted as a text-book in all the government *lycées* and public schools throughout France. At this period of his life Nodier devoted much of his time to the study of natural history. He only published two works bearing directly on that science; one, an *Essay on the Organs of Hearing in Insects*; the other, his *Bibliothèque Entomologique*; but nearly all his more mature works give evidence of great taste and knowledge in these branches of inquiry. His next work of importance was his *Napoleone*, published in 1800. It was written in defence of freedom, at that time rapidly dying out in France under the military despotism of Bonaparte. Many of the views and expressions were extremely distasteful to the First Consul, who, after keeping the poet in confinement for some months, banished him to his native town, and there put him under police surveillance. Nodier's studies now took a philological turn, and his *Examen Critique des Dictionnaires de la Langue Française* was a valuable contribution to a science at that time much neglected in France. For several years after this date, he led an unsettled and wandering life, till he found a resting-place at Dôle. He there began a course of lectures on literary subjects; gained great popularity as a lecturer and critic; and married Mademoiselle Charvès, a young lady of great beauty and accomplishments. For some years after his marriage Nodier continued to reside at Quintigny, near the Jura, till the necessities of his family, and the prospects of abundant literary employment, drove him to settle in Paris. For some years he contributed regularly to the *Journal des Débats*, and after the restoration of the Bourbons, became editor of the *Quotidienne*. In 1818 he published *Jean Sbogar*; in the following year his beautiful romance of *Thérèse Hubert*; in 1820 *Adèle*; in 1821 *Smarra*; and in 1822 *Trilby*. These works served to establish Nodier's fame, and soon after the appearance of the last mentioned of them he was appointed to the honourable position of librarian to the Arsenal. The duties of this office were severe, and the heavy exactions on his time by society left him comparatively little time for writing. Some of his best works, however, such as his *Dernier Banquet des Girondins*, his *Fantaisies du Docteur Néophobus*, and his *Franciscus Columna*, date after his appointment to the librarianship. He died on the 27th of January 1844, almost exactly ten years after his election as a member of the French Academy. Nodier was one of the most amiable, pure, and interesting among the French littérateurs of his day. It may be doubted if even his best works are of a texture to resist the tear and wear of all time. He wrote too much, and too variously, to insure himself a place in the front ranks of French genius; but it is hardly possible to deny that, had he concentrated instead of diffusing his powers, and written for the future rather than for the passing hour, his chances of immortality might have become certainties. An interesting Life of Nodier, by his friend François Wey, was published at Paris in 1845.

NOGENT-LE-ROTRON, a town of France, depart-

||
Nollekens.

ment of Eure-et-Loire, at the foot of a steep hill in a beautiful valley on the left bank of the Huisne, 33 miles W.S.W. of Chartres. On the hill are the ruins of an old castle, which was once the residence of the celebrated Sully. In the town are three churches, one of which is as old as the eleventh century, three hospitals, a chamber of manufactures, a college, and a court of the first resort. There are also dye-houses and fulling-mills, as well as manufactories of leather, serge, cotton yarn, sieves, &c. An active trade is carried on in linen, hemp, clover-seed, hay, cattle, and other articles. Pop. (1856) 6542.

NOIRMOUTIERS, an island of France, off the coast of the department of Vendée, separated from the mainland by a channel about one mile in breadth, which is nearly dry at low-water. Its length is about ten miles, greatest breadth three; area about seventy square miles, of which only about one-fifth is cultivated. This part is very fertile; and the rest of the surface is occupied chiefly by pasture ground and salt marshes. The island lies generally somewhat below the level of the sea, and is protected from inundation by embankments. The principal productions are salt, corn, beans, and some wine. On the east coast stands a town of the same name, which is well built, and has an old castle and a harbour. Pop. 7011.

NOLA, a town of Naples, in the province of Terra di Lavoro, stands on the plain between Mount Vesuvius and the Apennines, fourteen miles E.N.E. of Naples. It is ill built and dirty; contains several churches and convents, a college, hospital, and barracks; and is the see of a bishop. The town is of great antiquity, and is remarkable in Roman history for the resistance it offered to Hannibal in B.C. 216, who received his first check from Marcellus under the walls of this town. Nola is also remarkable as the place where Augustus died, A.D. 14; and in the fifth century it was the see of St Paulinus, by whom church bells were introduced. Many remains of antiquity have been found at Nola. Pop. 9600.

NOLLE PROSEQUI, a phrase used in judicial proceedings, where a plaintiff in an action does not declare in a reasonable time, in which case it is usual for the defendant's attorney to enter a rule for the plaintiff to declare, after which a *non prosequitur* may be entered. A *nolle prosequi* is esteemed a voluntary confession that the plaintiff has no cause of action; and therefore if a plaintiff enters his *nolle prosequi*, he may be amerced; but if an informer cause the same to be entered, the defendant may have costs. The phrase is derived from the words used in the formal entry of the withdrawal, in which the party agrees that he will not farther prosecute (*se ulterius nolle prosequi*).

NOLLEKENS, JOSEPH, a distinguished English sculptor, was born in London on the 11th of August 1737. His father, a native of Antwerp, was a painter by profession, and is mentioned by Horace Walpole, under the name of "Old Nollekens," as an artist of some repute. He died whilst Joseph was still very young; and his widow having married again soon after his decease, the education of the youthful sculptor was much neglected. In his thirteenth year we find him in the studio of Scheemakers, where he exhibited his passion for his art by drawing and modelling early and late with the utmost assiduity. As his powers expanded, he became repeatedly a successful candidate for the prizes offered to rising genius by the Society of Arts. In his twenty-third year we find him in Rome, friendless, and nearly reduced to want, but enthusiastically pursuing his vocation. He modelled and carved in stone a bas-relief, which brought him ten guineas in England; and in the following year his group of "Timoclea before Alexander," in marble, was honoured by the Society of Arts with a premium of fifty guineas. This success placed him above absolute dependence; and he was now noticed by the artists in Rome, particularly Barry, and also by some English visitors, amongst whom were Garrick and Sterne. The

Nollekens.

great English actor recognising him one day in the Vatican, invited him to breakfast next morning, and ended by sitting to him for his bust, for the model of which Garrick paid twelve guineas to the artist. Sterne likewise sat to him at Rome; and the bust of the wit, which is in terra-cotta, is considered an admirable likeness. To the last hour of his life Nollekens alluded to it with pleasure. "Dance," he used to say, "made my picture with my hand leaning on Sterne's head; he was right." He was liberally patronized by his countrymen who annually migrated to the capital of Italy, and for whom he executed many considerable works in marble, of which "Mercury and Venus chiding Cupid" are considered as the best. For all his productions he received immediate and liberal payment. Early misfortunes had made Nollekens acquainted with privation. Being an economist from necessity, he became frugal from habit; and this continued to influence his conduct when the necessity for parsimony no longer existed. He lived at Rome in a very humble manner, and, after ten years of profitable study, he returned to London comparatively rich. Nollekens was now prepared to commence business upon his own account, and accordingly he took a lease of extensive premises in Mortimer Street. The busts of Sterne and Garrick had spread his fame in his native country, and he no sooner opened his doors than orders came in in abundance. In 1771 he was admitted an associate of the Royal Academy, and in the following year was elected a member, much to the satisfaction of George III., who soon afterwards honoured the artist by sitting for his bust. Nollekens about this time married a lady who was the friend of Samuel Johnson, and, if report may in aught be credited, the great critic was not insensible to her charms. Nollekens was fully aware that his strength lay in busts; and as this line of art was an exceedingly profitable one, it may readily be supposed that his time and talents were principally devoted to it. Amongst his sitters were the great, the beautiful, and the titled of the land; and his profits were commensurate with the condition of his employers. He also found leisure to work out, slowly and with much care, marble groups and statues, amongst which may be mentioned those of "Bacchus," "Venus taking off her sandal," "Hope leaning on an urn," "Juno," "Pætus and Arria," and "Cupid and Psyche." His portraits were excellent, and there was generally a gentleness in the expression, and a gracefulness in the handling, which never failed to please. The likenesses of his busts were acknowledged by all, and the prettiness of the statues could not fail to be as generally admitted. But original vigour was wanting. He was one in whom the merely imitative faculty greatly surpassed the imaginative. The want of imagination Nollekens partially supplied, however, by a diligent study of the antique; and hence, whilst every statue surpassed its predecessor in delicacy of workmanship, the artist only attained eminence by incessant labour. During a period of ten years, from 1776 to 1786, he exhibited sixteen busts, five statues, and four groups, some of which were not in marble. The statues were those of "Juno," "Diana," "Adonis," "Cupid," and "Mercury," in which he followed the beaten track, without attempting anything new. Amongst his monumental effigies may be mentioned that which commemorated the three commanders who fell in Rodney's great battle of the 12th April 1782. From his "Venus," and other statues of that description, we pass on to those productions which were more suitable to the genius of the artist. The ten years which followed 1800 were the busiest in the life of Nollekens; for although he was between sixty and seventy years of age, he continued to work with the same diligence and skill as in his youth. Upwards of fifty busts proceeded from his chisel, besides nearly a score of groups and statues. Amongst the former were the far-famed heads of Pitt and Fox, those of the Prince of Wales,

Nombre-de-Dios
||
Nominalists and Realists.

afterwards George IV., Dr Burney, the Marquis of Stafford, the Duke of Bedford, and others. Of the twenty statues and groups, the statue of Pitt for Cambridge attracted most attention at the time. The "Venus anointing herself," however, was the favourite work of Nollekens, though it is deficient both in originality and in propriety of action. The workmanship of the statue, however, is very fine. From 1810 till 1816, the last year of his exertions, he modelled some thirty busts, not a few of which are ranked amongst the most valuable of his works. The principal heads are those of the Duke of York; Lords Castlereagh, Aberdeen, Erskine, Egremont, Liverpool; Canning, Perceval, Benjamin West, and Thomas Coutts the banker. Nollekens died on the 23d of April 1823, leaving a fortune of some two hundred thousand pounds. (Cunningham's *Lives of British Painters, Sculptors, and Architects*, vol. iii.) (J. F. S.)

NOMBRE-DE-DIOS, a town of Mexico, department of Durango, and 45 miles S.S.E. of the town of that name. In the vicinity there are rich silver mines; but the principal resources of the place are derived from the sale of a liquor called *mescal*, distilled from the aloe. Pop. 7000.

NOMINALISTS AND REALISTS, two opposing sects among the scholastic philosophers, celebrated for the bitter and even bloody hostility with which they maintained their disputes. The contest turned upon the nature of general terms, or *universals*. While both parties agreed that the object of the science of logic was universals, they differed upon the grand question as to whether these universals were *real* things or mere *names*. One party espoused the latter opinion, and went by the name of Nominalists; the other adopted the former view, and received the name of Realists. The Nominalist cited Aristotle in behalf of his position; the Realist adduced Plato in favour of his. It becomes therefore necessary, in order to get to the root of this famous controversy, to advert to the doctrines of those ancient masters respecting common notions or ideas. According to the opinion of Plato, common terms, as representative of the actual and eternal ideas of the Divine mind, according to which all particular existences are formed, have a real, permanent existence. The partial exponents of these ideas, as manifested in individuals, he held to be unreal and illusory; and that the only proper realities were those general notions or ideas denoted by the term *universals*. Words, according to Plato, are the means whereby we ascend to a clear and vital perception of things, and behind every common term there lurks an unquestionable reality. To seize upon this reality is accordingly the business of his dialectics. With Aristotle, again, whose philosophy was fundamentally distinct from his master's, the business of dialectics is to treat of the manner in which our minds discourse of things: words, according to him, are the representatives of our thoughts; and class words set forth in speech our notions or generalized conceptions of individuals. He therefore denied the eternal existence of Plato's ideas, but admitted with him the existence of those ideas in every individual of the species of which they formed the proper essence. As the phrases went among the schoolmen, Aristotle maintained *universalia in re*; Plato, *universalia ante rem*; the Nominalists, *universalia post rem*. Logic, with Aristotle, was the science of names and notions; with Plato it was more the science of names and realities. With Aristotle logic was an end in itself—it was the science of the laws of discursive thinking; with Plato it was simply a means whereby the eternal and only realities which lay concealed behind universals were to be laid hold of. It is curious, however, that "different philosophers," according to Sir W. Hamilton, "have maintained that Aristotle was a Realist, a Conceptualist, and a Nominalist in the strictest sense." (Hamilton's Edition of Reid's Works, p. 405, note.)

Nominalists and Realists.

At a very early period in the history of the church the Platonic ideas of being and unity had become inseparably connected with the mysteries of the Christian religion. The science of logic, as taught in the *Organum* of the Stagyrte, who was, indeed, the true founder of the science, was expounded by the doctors of the schools according to the principles of Plato, which had no proper connection with it. This practice continued until the times of St Anselm, about the end of the eleventh century, when a disputed passage in Porphyry's Introduction to the *Organum* of Aristotle, respecting the disagreement of the Platonists and Peripatetics on the nature of genera, brought matters to a crisis. Roscelinus, or Roscelin, a canon of Compiègne, maintained that the notions of universals, of genera, and species were possessed of no reality,—were nothing but mere words (*flatus vocis*) employed to designate qualities common to different individuals. By this man, and in this manner, was Nominalism founded. Although apparently a trifling dispute in itself, the theory of ideas was nevertheless a fundamental one in the scheme of human knowledge. The controversy thus excited by the canon of Compiègne had accordingly an extensive bearing. If every genus is only a mere word, it follows that individuals are the only realities, and that the senses are at bottom the only sources of knowledge. And not only so, but on this theory no absolute affirmation respecting truth is possible, for such an affirmation involves of necessity a general idea, which, *ex hypothesi*, is destitute of real validity. Hence we have scepticism at the next remove. Among churchmen, of course, all such disputes partook more or less of a theological character. The Nominalist doctrine, by denying a real validity to abstract ideas, was charged with necessitating the denial of the realities of unities, and, in particular, of the great unity which forms the basis of the Holy Trinity. If the Trinity represented only a nominal unity, then it was pretty obvious that Roscelinus, the Nominalist, was a very dangerous person indeed. The poor canon had therefore to retract, on pain of death, at the Council of Soissons in 1092. St Anselm was the first to attack the position of Roscelinus, in a work on the Unity of the Trinity, but with a degree of temperance all his own, and with a realistic creed different from that of the Realists of the schools. Seeing that Nominalism and heresy had now become synonymous, it behoved philosophic churchmen to crush the error. William of Champeaux, in order to do the work effectually, rushed straight to the opposite extreme, and, as the founder of scholastic Realism, maintained that universals, so far from possessing a merely nominal existence, were in point of fact the only real entities. Genera, according to him, individualize themselves in particular beings in such a manner that individuals differ only by the variety of their accidents, but are identical as to their essence or real nature. A few steps further and we have pantheism. Such, then, were the alternatives to which the speculations of Roscelinus and William of Champeaux reduced the thinkers of that time. Nominalism and scepticism, Realism and pantheism—such was the dilemma. Abelard, the illustrious pupil of the founder of Realism, like a wise man, chose a middle course in preference to the horn of either extreme. He ascribed a reality both to individuals and universals, but a reality differing in the case of each. Individuals had, he maintained, an essential existence, and universals an existence ideally real. Genera were abstracted from particulars, and existed in the mind in the form of notions, or (as we call them now) *concepts*, and were held together and expressed by words called *general terms*. Hence the theory termed *Conceptualism*, or conceptual Nominalism, which was really the one maintained by all succeeding Nominalists, and is the doctrine of ideas generally believed in at the present day. Abelard displeased his proud master, William, by this middle

Nomsz. course, and, as so often happens, gave satisfaction to no one. Realism accordingly triumphed in silence during the second stage of middle-age scholasticism. (See Cousin's Introduction to the unpublished works of Abelard, and his *Fragments de Phil. Scholast.*) Nominalism had well-nigh died out, when William of Occam or Ockham, an English Franciscan, and pupil of Duns Scotus, came forward in the fourteenth century to revive its decadent glory. This "invincible doctor" attacked the Realists with great spirit, and raised the doctrines of the Nominalists into greater repute than they had ever before enjoyed. Nominalism, however, was no longer upheld by Occam and his followers in its absolute form: Conceptualism is the appropriate designation for their theory. The contest between the opposing parties was now conducted with a virulence and ferocity altogether unworthy of philosophers. The strife raged in the schools of Britain, France, and Germany with the greatest fury. When words would not carry conviction, the passionate doctors had recourse to blows: when argument and patience were alike exhausted, the invincible combatants drew upon one another, and ended the quarrel in blood. The doctor *invincibilis* himself, after espousing the cause of Philippe le Bel, King of France, and of Louis of Bavaria, against the Popes Boniface VIII. and John XXII., died at Munich, "persecuted but not subdued," about the middle of the fourteenth century. Realism, as then identified with the cause of the Pope and the church, continued to prosper in Italy under the patronage of the Roman See; while Nominalism, which, from the influence of its most stanch supporter, had become identified with the political movement then agitated against the church, was generally received throughout the greater part of the European continent. But the time came when not only the University, but the King, of France issued edicts of extermination against the Nominalists. Their writings were ordered by Louis XI., in 1473, to be seized and bound in the libraries in iron chains; but after some time the edict was mitigated, the exiled sect was permitted to return, and Nominalism gained the ascendancy in France as in Germany. The fruitless and fatal consequences of these wranglings gradually became apparent. Scholasticism, with its endless subtleties and perverse ingenuities, became suspected, and a disposition towards mysticism gradually made its appearance among thinking men. (See MYSTICISM.) The revival of letters, and the advent of the Reformation, eventually put an end to the fiercest controversy known in the annals of philosophical speculation. Among the most celebrated Nominalists not already mentioned, were,—Durand of Saint Pourçain, John Buridan, Robert Holcot, Gregory of Rimini, and Henry of Hesse, in the fourteenth century; and Matthew of Crochove, Peter D'Ailly, Gabriel Biel, and Raymond of Sebonde, in the fifteenth. Among the Realists not already cited may be mentioned Henry of Gand, Walter Burleigh, Thomas of Strasburg, Marsile of Inghen, and Thomas of Bradwardine,—all in the fourteenth century. In addition to the ordinary histories of philosophy, the reader may consult with profit *Ueber Nominalismus u. Realismus*, von Erner, 1842; also the *Dictionnaire des Sciences Philosophiques*. (J. D—S.)

NOMSZ, JAN, a voluminous Dutch author, was born at Amsterdam in 1738, and renounced commerce to devote himself to literature. An epic poem, entitled *William I., the Founder of the Freedom of the Netherlands*, brought him into notice in 1779. Stimulated by his success, his active brain continued to produce numerous works on different subjects. He wrote satires, poetical epistles, historical sketches, newspaper articles, and translations from the French. He also composed or translated more than forty plays, which acquired great popularity on the stage of his native city. Yet all these successful efforts did not prevent him from falling into misfortune, losing his self-respect, and

bringing his life to a calamitous close. He died in an hospital in 1803.

NONAGESIMAL, or **NONAGESIMAL DEGREE**, is the highest point, or ninetieth degree of the ecliptic, reckoned from its intersection with the horizon at any time; and its altitude is equal to the angle which the ecliptic makes with the horizon at their intersection, or equal to the distance of the zenith from the pole of the ecliptic. It is much used in the calculation of the parallaxes of the moon. (See ASTRONOMY.)

NONAGON, a nine-sided polygon. (See GEOMETRY.)

NONCONFORMISTS, the name by which Protestant dissenters from the Church of England are generally known. Their existence dates almost as far back as that church itself. The attempt made by Henry VIII. to constitute an Anglican church differing from the Roman Catholic church only on the point of supremacy, succeeded as long as his own energy and boldness remained to support it. A system which had burnt Reformers as heretics, and hung Papists as traitors, was not likely to find much favour in a country where the popular zeal ran high in favour either of the old opinions or the new. Henry's system accordingly died with its founder; and it was reserved for the pious and courtly Cranmer to have the honour of laying the first stone of the proud edifice of the Church of England. The government and the Protestants required the mutual support of each other; and in order to a union, concessions were made on both sides. They took a middle course between Rome and Geneva, and laid the foundation of the Church of England. Her principles of theology were mainly Protestant; her prayers and thanksgivings savoured of the ancient breviaries; her government was episcopal; and the king was her head. Despite the ingenuity and good design of this compromise, it is obvious that it was calculated to give scandal not only to zealous Catholics by going too far, but also to zealous Protestants by not going far enough. It was from the latter class, accordingly, that the Nonconformists and Puritans of England afterwards sprung, who were ultimately destined to exert a powerful influence over the political as well as the religious institutions of the kingdom. If in the days of Edward VI. the discontent of this party caused the government not a little annoyance, the fiery trials through which they had to pass during the succeeding reign were not calculated to allay their scruples. The cruelties of Mary drove immense numbers of Protestants to the Continent for safety, and the majority of them found an asylum in Switzerland and Germany. A portion of them settled at Frankfort, and resolved, after some deliberation, to adopt the Genevan service-book in preference to that of King Edward. Not a few of the exiles in Strasburg and elsewhere opposed this step; and Frankfort became the theatre of a contest between the rival systems of Episcopacy and Presbytery. John Knox, who had ministered for a time to the exiles at Frankfort, was forced to flee from the scene of strife, and Episcopacy triumphed. From this dispute dates the existence of the *Puritans* or *Nonconformists*; both epithets having originated in the attitude assumed by the opponents of the Church of England. When Elizabeth came to the throne the exiles returned to England, and brought their ecclesiastical disputes along with them. The battle now began in real earnest on English soil, but no concession could be obtained from Elizabeth. She endeavoured, on the contrary, by the most vigorous policy to check the progress of this numerous, active, earnest-minded party. She occasionally even sent the more stubborn of them to prison; but so strongly were they attached to her as the mainstay of the Reformed churches, that they did not cease to pray, from the gloom of the dungeon, for the safety of her person and the victory of her arms. "The Nonconformists," says Lord Macaulay, "rigorously as she treated them, have, as a body, always

Nonagesimal
||
Nonconformists.

Nonconformists.

venerated her memory." (*History of England*, vol. i.) The acts passed during Elizabeth's reign for the suppression of Nonconformity were both numerous and severe. By the Act of Uniformity (1 Eliz., c. 2), rigorous penalties were enacted against all who should perform divine worship after any other mode than that prescribed in the Book of Common Prayer. From 1558 to 1565 this law was only partially observed, but from the latter year it began to be applied in all its force. Many of the Nonconformists lost their preferments, for they had not as yet judged it advisable to separate themselves from the church. By the act 23 Eliz., cap. i., sec. 5, the Puritans were subjected to heavy fines as often as they indulged their antipathy to the Established Church by absenting themselves from its worship. The rigour of these fines was even increased by the statute of 29 Eliz., cap. 6, secs. 4, 6; and by an act of 3 Jac. I., cap. 4, sec. 11, this obnoxious enactment was rendered still more tyrannical and severe. The last statute of Elizabeth's reign which weighed heavily on Nonconformity in England was 35 Eliz., cap. 1. It converted fines into imprisonment, and even perpetual exile from the kingdom, as the penalty of non-attendance at the Established Church, or of the countenancing of conventicles. It should be noted, however, that while those provisions severely affected the Protestant Nonconformists, they were perhaps directed mainly against the Roman Catholics. During this entire reign the Puritans were not without great strength and influence in the House of Commons—an influence, moreover, that continued to increase despite the rigorous policy adopted for their suppression. And, after all, the demands of the more reasonable among them were not so very exorbitant. Not a few of them would have rested satisfied with the removal of such rites and ceremonies as they deemed a departure from the purity of Christian worship as revealed in the Scriptures. Others, with Cartwright of Cambridge at their head, were anxious for Presbytery rather than Episcopacy; while a third party—the Brownists or Independents—advocated the entire separation of church and state. The death of Elizabeth came in 1603, however, and no concessions had as yet been made to the demands of the Puritans. The high hopes raised by that much-wronged party on the accession of a Presbyterian to the throne were not destined to be realized. James I. condescended to hold conference with the Nonconformists at Hampton Court, but was more anxious to impress them with a sense of his superiority in theological disputation, than to listen to their wrongs with a view to their amelioration. The king was ingenious, but the sturdy Puritans could not be convinced. They were accordingly dismissed with insults, only to have fresh temporal and spiritual penalties issued against them in the Book of Canons of 1604. The acts of 3 Jac. I., cap. 4, and of 21 Jac. I., cap. 4, were passed to circumscribe still more the liberties of the nonconforming community, and to render their bondage yet more galling. Still, Puritanism continued to make progress in England, and the Arminianism of King James added greatly to the number of the disaffected in the bosom of the Church of England. The policy of Charles I. showed no improvement on that of his predecessors; and his bitter antagonism to the Puritans found a zealous supporter in the person of the notorious Archbishop Laud. To escape the atrocities of the Star Chamber and of the High Commission Court, not a few sought safety in voluntary exile to Massachusetts Bay, where they founded a colony, of which men still know something. But the sad relief of expatriation was soon denied them by express proclamation. Hundreds of Puritan clergymen were ejected during this reign for their hostility to the *Book of Sports*: Calvinism was denounced by the king and court; and fresh restrictions were laid upon Nonconformist preaching. Human patience, however, has its limits; and a day of dark retribution came, when the down-trodden people of

England rose in their wrath to right themselves. Laud was beheaded in 1644: five years afterwards his royal master shared the same fate: the Parliament had abolished Episcopacy, and Presbyterianism had its short hour of triumph. During the Protectorate all manner of sects were tolerated: Independency prevailed in the army: Baptists and Quakers flourished: the most unheard-of visionaries sprung up; but Episcopacy remained proscribed.

The Restoration of 1660 placed Charles II. on the throne, and brought back the old established religion. A new "Act of Uniformity" was passed (14 Car. II., cap. 4) in August 24, 1662, excluding from its communion all non-subscribers to the doctrines of the church, and otherwise subjecting them to much suffering and cruel restriction. It is from this date that the title of Nonconformists comes most into prominence. On this occasion no fewer than 2000 ministers of the church resigned their livings rather than conform to the Thirty-nine Articles. During the same reign the Conventicle Act (16 Car. II., cap. 4), the Five Mile Act (17 Car. II., cap. 1), the Corporation Act (18 Car. II., cap. 1), and the Test Act (25 Car. II., cap. 2), fell either directly or indirectly with much severity upon the Protestant Nonconformists. The statute of 22 Car. II., cap. 1, was passed with a view to annihilate conventicles by means of fines of minute rigour and uncompromising strictness. The opening of the reign of James II. brought no relief to the Nonconformists; but, to their no small astonishment and temporary delight, the 4th of April 1687, witnessed James's arbitrary Declaration of Indulgence. This proved, however, to be only a move more cunning than wise on the part of his unfortunate Majesty, to unite the Puritans and the Church of Rome in a coalition against the Church of England. All classes of Nonconformists were now exempted from penal laws: Protestant and Roman Catholic alike enjoyed public toleration. The Protestant dissenters soon discovered, however, that their spiritual privileges had, in point of fact, been abridged rather than extended by this indulgence. If they were flattered by the favour shown them by the court, they soon discovered they had purchased this hollow honour only at the expense of treating the court religion—the religion of Rome—with a becoming tenderness and respect. This, to a genuine Puritan, was worse than gall and wormwood, and it ultimately produced its effect. The blessings of a better toleration were reserved for the reign of the Prince of Orange. By the Toleration Act of 1 Wm. III., cap. 18, all Protestant dissenters, except those who denied the Trinity, were relieved from the penal statutes to which they had been subjected. The benefits of this act were afterwards somewhat circumscribed by the Occasional Communion Bill and by the Schism Bill. The latter was repealed, however, in the reign of Geo. III. (19 Geo. III., cap. 24); and the Corporation and Test Acts were abolished in the reign of Geo. IV. (9 Geo. IV., cap. 17). These and other improvements, together with the passing of the statutes relating to registration and marriage, have now placed dissenters in England in the enjoyment of full liberty of conscience in the matter of religious worship. (Special and detailed accounts of the various sects of the Nonconformists will be found under the articles BAPTISTS, INDEPENDENTS, METHODISTS, PRESBYTERIANS, and QUAKERS. See Price's *History of Protestant Nonconformity in England*, 2 vols., London, 1838; and Macaulay's *History of England*.)

NONES, one of the three divisions of the Roman month. (See CALENDAR.)

NONJURORS, those clergymen who refused to take the oaths to the new government after the Revolution, and who were in consequence subject to certain incapacities and liable to certain penalties. (See BRITAIN, *History of*.)

NONNUS, a Greek poet, was a native of Panopolis in

Nones
||
Nonnus.

Noaaheeva, Egypt, and flourished in the fifth century A.D. It is likely that he was still a pagan when he wrote the former of his two extant works, the epic poem *Dionysiaca*. Then having been converted to Christianity, and probably resolving to consecrate his talents to the support of the new faith, he composed his hexameter paraphrase of the Gospel of St John. The epic is chiefly characterized by a cumbersome and disjointed plot, which runs lumbering on through forty-eight books amid much inflated verbiage and numerous inappropriate episodes. The paraphrase is valuable only on account of some of the various readings which it furnishes. The latest edition of the former of these works is that of F. Graefe, in 2 vols. 8vo, Leipsic, 1819-26. The latest edition of the latter is that of Passow, Leipsic, 1834.

NOOAHEEVA, **NOUHEVA**, or **NOUKA-HIVA**, the largest of the Marquesas Islands, is in S. Lat. 8. 53., W. Long. 139. 49.; and has a length of about 18 miles. The surface is rugged and mountainous, and the coasts steep; the whole island being apparently of volcanic origin. The soil is rich and deep in the valleys, but on the hills it is thin, producing only tufts of coarse grass. Bananas and cocoa-nut trees grow in abundance; but as the inhabitants, who are very lazy, are supplied with food by the spontaneous productions of the soil, the only article that is cultivated is tobacco. The people are of a dark copper colour, and live in huts of wood or cane raised above the ground on a platform of stones. There are several tribes in the island, who are very warlike, and are believed to be cannibals. No trace of any religion is to be observed; and the utmost licentiousness seems to prevail. The population is variously estimated from 8000 to 18,000.

NOODT, **GERARD**, a celebrated jurist, was born at Nimeguen in 1647. He began his studies in his native town, and finished them at Franeker, by taking his degree in law. A successful defence of two criminals, who were arraigned at the bar for murder, first gave him a start in his profession. After passing through several successive grades of promotion, he was ultimately appointed a law professor at Leyden. But it was in the character of a writer on jurisprudence that his talents and acquirements were chiefly displayed. His Latin style, modelled after the best writers, was pure and precise; he had an intimate acquaintance with the laws, manners, and customs of ancient Rome; his speculations were guided by a simple desire for truth, and by a wary dread of dogmatic conjecture; and his political opinions were animated by a spirit of Catholic toleration. Accordingly his numerous works, as they successively appeared, rose to the rank of standard authorities. Two of the most popular among them were translated into French by Barbeyrac, and appeared at Amsterdam in 1707 and 1714, under the respective titles of *Pouvoir des Souverains*, and *Liberté de Conscience*. Noodt was still actively engaged in adding to the number of his treatises when he was cut off in 1725. His entire works, accompanied with a Life, were published by Barbeyrac, in 2 vols. fol., Leyden, 1735, and reprinted at the same place in 1760.

NOOTKA SOUND, an inlet of British North America, on the W. coast of Vancouver Island; N. Lat. 49. 35., W. Long. 126. 35. It stretches in a N.N.E. direction for 10 miles, and forms a number of smaller bays and coves. There is a wooded island in the centre; and the greatest breadth of water is not more than a quarter of a mile. The shores are rocky, and the bay forms a very safe harbour, but is not capable of accommodating more than two vessels.

NORBERG, or **NORDBERG**, **GEORGE**, the historian of Charles XII. of Sweden, was born at Stockholm in 1677. Having entered into holy orders, after the usual course of study at Upsal, he was appointed almoner to the army of Charles XII. in 1703, and was promoted to the office of chaplain to the king in 1707. He continued to hold this latter post till he was carried away from the field of Pultawa

in 1709 to a captivity of six years in Russia. All this while it had been his custom to keep a record of the principal incidents that came under his observation. Accordingly, several years after he had been settled down in a pastoral charge in his native city, he was employed by Queen Ulrica Eleonora to write the history of her deceased brother, Charles XII. The work, after undergoing royal inspection and revision, was published in 2 vols. fol., Stockholm, 1740, and reappeared in a French translation in 3 vols. 4to, the Hague, 1742. Two years after this latter date the author died at Stockholm.

NORCIA, a town in the Papal States, delegation of Spoleto, in a lofty valley near the source of the Nar, 17 miles E.N.E. of Spoleto. It has a considerable trade in pigs, oil, wine, and other agricultural produce. Pop. 4000.

NORD, a department of France, so called from its being the most northerly in the country, lies between N. Lat. 49. 58. and 51. 5., E. Long. 2. 7. and 4. 23.; and is bounded on the N. by the German Ocean, N.E. and E. by Belgium, S. by Aisne and Somme, and S.W. by Pas de Calais. Its length from N.W. to S.E. is about 124 miles; the breadth varies from 2½ to 39 miles; area, 2192 square miles. The whole surface consists of a flat and monotonous plain, slightly sloping towards the N.E., and diversified with a few hills, which do not exceed 400 feet in height. The south-eastern part of the department is occupied by the northern slopes of the mountains and the forests of Ardenne; and throughout the whole extent of the country cultivation is carried to the top of the highest elevations. The coast of the German Ocean is formed by a range of sand-hills, called *dunes* or downs, and the land beyond is little, if at all, above the level of the sea. The principal rivers flow N.E. towards the German Ocean, and owing to the flatness of the country are of a very sluggish nature. The principal of these are,—Ysser, Lys, Scarpe, Scheldt, and Sambre. The Aa, which has a N.W. direction, separates the departments of Nord and Pas de Calais. The soil is generally very good; and near the coast, where the low land is of a marshy nature, a skilful system of drainage has rendered that not only fit for cultivation, but has reclaimed from the water a tract of great fertility. Part of this district, called the Watteringhes, has been drained from a very early period by canals of various sizes,—some natural and some artificial,—which convey the water of the marshes into the sea at low-water. This district comprises an area of 195,321 acres, and is divided into four sections, each under the superintendence of special commissioners to see that the works are kept in repair. The other portion of the marshy ground lies partly in France and partly in Belgium, and is known by the name of Moeres. It consists of a larger and a smaller Moere—the former having an area of 7664 acres, of which 2944 are in France; while the latter extends only to 433 acres. This ground has on several occasions been drained, and again laid under water for the protection of the frontier, but was finally recovered from the sea in 1826. The soil of Nord consists of rich alluvial earth in the northern part, and towards the south is of a calcareous and clayey nature. The principal minerals are iron, coal, marble, paving-stones, potters' clay, &c. Cultivation is more largely and better carried on here than in most other parts of France; about 890,000 acres are occupied by arable land, 235,000 by meadows, 86,500 by wood, &c. The crops principally raised consist of wheat, rye, barley, oats, pulse, hemp, flax, tobacco, hops, &c. Pastoral occupations are also largely pursued. The horses, estimated at 80,000, are strong and fit for farm labour; the horned cattle, of which there are 230,000 head, are of one of the best breeds in France; and the 240,000 sheep of the department produce excellent wool. There are also 75,000 pigs and 7000 goats. The mineral operations carried on in this department are probably the most extensive in

sen.

France, consisting principally in the working of coal and iron mines. The manufactures are many and varied; linen, cotton, and woollen stuffs of all kinds; lace, tulle, cambric, and lawn; sugar, starch, soap, oil, glass, paper, earthenware, ropes, leather, cannon, &c. The commerce of the department is also very great, consisting of the exportation of the produce of the soil and of the manufactures, and in the importation of cotton, wool, flax, tobacco, wine, brandy, timber, &c., which are received from foreign countries and from the French colonies. There are two seaports on the German Ocean, Dunkirk and Gravelines,—at the former of which the maritime trade is chiefly carried on. The people near the coast are employed to a large extent in the herring fishery; and many vessels are sent out from Dunkirk and Gravelines to the whale and cod fisheries. In no part of France are the internal communications so much facilitated by roads and canals as in this department, where there are 15 imperial roads, extending over 360 miles; 17 departmental roads of 176 miles; besides 6 navigable rivers and 23 canals, with a total length of 350 miles. There are also 4 principal railways, extending over 143 miles. Nord forms the diocese of the Archbishop of Cambrai, and contains 5 Protestant places of worship and a Jewish synagogue. It has a court of appeal, 7 courts of primary jurisdiction, 4 tribunals of commerce, and 7 councils of *prud'hommes*. The educational institutions are,—a primary normal school at Douai, 2 academies, 15 communal colleges, 934 public primary schools, &c. There are also 47 hospitals, 2 deaf-and-dumb institutions, 3 lunatic asylums and other charitable establishments, 9 prisons, and 13 fortified places. The capital is Lille; and the department is divided into 7 arrondissements as follows:—

	Cantons.	Communes.	Population, 1856.
Lille	16	132	404,279
Douai	6	66	106,155
Dunkirk	7	59	105,717
Hazebrouck	7	53	102,734
Avesnes	10	153	150,523
Valenciennes	7	81	163,082
Cambrai	7	118	179,863
Total	60	662	1,212,353

NORD, CÔTES DU. See CÔTES DU NORD.

NORDEN, a town of Hanover, in the province of Aurich, on a canal leading to the Bay of Leisand, in the German Ocean, which is 4 miles off, 16 miles N. of Emden, and 15 N.W. of Aurich. It is an ancient and well-built town, with a large market-place planted with fine trees. There are churches belonging to the Lutherans, Reformed Church, Roman Catholics, Moravians, and Mennonites; a synagogue; an hospital, which was formerly a convent; and a school. Norden has numerous breweries; manufactories of cloth, leather, and tobacco; and a considerable shipping trade. Markets for horses are held here. Pop. (1852) 6188.

NORDHAUSEN, a town of Prussian Saxony, in the government of Erfurt, stands on the Zorge, at the foot of the Seyersberg, a branch of the Harz Mountains, and at the head of the fertile valley called the *Guldene Aue*, or Golden Valley, 38 miles N.N.W. of Erfurt, and 49 W. of Halle. It has an antique appearance, and is surrounded by walls and towers, with seven gates. There are a Roman Catholic and several Protestant churches, one of the latter containing two paintings by Cranach; a town-hall; a theatre; 4 hospitals; and several schools. Nordhausen contains distilleries, which are among the largest in Germany; besides tanneries, woollen factories, soap-works, oil-mills, and manufactories of linen, hats, scaling-wax, vitriol, and chemical

substances. An active trade is carried on here in corn and cattle. Wolf, the famous classical scholar, was born in the neighbourhood of Nordhausen. Pop. 14,960.

NORDHEIM, a town of Hanover, in the province of Hildesheim, on the left bank of the Ruhme, 12 miles N. of Göttingen. It is well built, and defended by walls. There are saw-mills, and manufactories of cloth, leather, shoes, and tobacco. Some trade is carried on in timber. In the neighbourhood there are sulphureous springs. Pop. (1852) 4679.

NORDKÖPING, or NORRKÖPING, a town of Sweden, in the *län* of Linköping, near the mouth of the Motala, in the Bravik, an inlet of the Baltic, 24 miles N.E. of Linköping, and about 90 S.W. of Stockholm. It has a beautiful situation on both sides of the river, which here incloses two islands, and is crossed by several bridges. The streets are broad, straight, well paved, and lined with neat houses, generally only two storeys high, built some of wood and some of stone. There are three churches, a town-hall, a synagogue, an hospital, and several schools. Manufactures of linen, cotton, and woollen cloth, paper, starch, soap, tobacco, sugar, brass, hardware, &c., are carried on here; and there are docks for ship-building, in which many fine steamers have been constructed. A considerable trade is carried on in the exportation of iron, grain, and manufactured articles. Pop. about 12,000.

NORDLINGEN, a walled town of Bavaria, in the circle of Swabia, on the Eger, 39 miles N.W. of Augsburg, and 48 S.W. of Nuremberg. It has 4 churches, one of which, completed in 1505, has a tower 268 feet high, and contains in the interior a fine organ and some paintings; a town-hall; an hospital; and several schools. Manufactures of carpets, woollen and linen cloth, leather, and glue, are carried on here; and the place is remarkable for its geese, in the feathers of which, as well as in cattle, an extensive trade is carried on. Nordlingen is historically important for the victory gained here in 1634 by the Austrians and Bavarians over the Swedes. A fresco painting of the battle adorns the town-hall. Pop. 7000.

NORE, a part of the estuary of the Thames, to the E. of Sheerness, and about 50 miles below London.

NORFOLK, an English maritime county, the most easterly and the fourth in territorial extent in the country, and tenth as regards population. It is bounded on the N. and N.E. by the German Ocean; on the N.W. by the estuary called the Wash; and on the S. the rivers Waveney and Little Ouse divide it from Suffolk; while the Great Ouse, the Wilney, and the Nene separate it from Cambridgeshire. Its greatest length is about 70 miles from E. to W., and the broadest part is 42 miles from N. to S. It lies between 50. 17. and 52. 56. N. Lat., and 0. 1. and 1. 45. E. Long.; is about 180 miles in circumference; and contains within the county proper (as distinguished from the registration county) 1,354,301 acres; is divided into 33 hundreds and 740 parishes, including the city of Norwich, which is a city and county in itself.

The population, according to the returns at the six Census decennial enumerations, amounted in 1801 to 271,125, in returns 1811 to 288,305, in 1821 to 339,885, in 1831 to 384,142, in 1841 to 405,124, in 1851 to 433,716.

The census of 1851 returns the registration county as follows:—

Area in statute acres.	Inhabited Houses.	Uninhab. Houses.	Houses building.	Population.	Males.	Females.
1,300,311	91,144	3360	447	433,716	210,769	222,957

The amount of real property assessed to the property and income tax in 1851 was L.2,463,893, and the amount

Nordheim
||
Norfolk.

¹ These computations are founded on the principle adopted at the last census, which was taken in accordance with statutes 2 and 3 Will. IV., c. 64, and 7 and 8 Vict., c. 61, which altered the limits of counties, and made them consist of groups of registration districts, in general identical with poor-law unions. All isolated portions of counties are now considered part of the county surrounding them, or with which they have the greatest common boundary. Norfolk, by this arrangement, has been diminished in area, the extensive parish of Upwell having been detached from it and added to Cambridgeshire.

Norfolk. assessed to the relief of the poor for the year ending March 1850 was L.1,865,216. The expenditure of the county for 1856 was—

For Gaols.....	L.6,407	18	10
Administration of Justice.....	4,201	5	10
Lunatic Asylums.....	1,770	17	7
Coroners.....	1,071	14	9
Militia and Artillery.....	1,124	18	6
Miscellaneous.....	2,623	10	11
	17,200	6	5

The county rate levies amounted to.....L.13,393 0 0
And the receipts from Government to..... 3,544 0 0

The births in 1851 were 14,345, deaths 9384, and marriages 3177. The places of worship were—belonging to the Church of England, 719; and sittings, 187,210: belonging to other denominations, 722; and sittings, 125,703.

There are about 100 endowed schools in connection with the Church of England, and above 1200 day schools of all denominations. The educational census gives the number of children of all ages at school—boys, 26,694; girls, 26,299. The Sunday schools are returned as 782; and Sunday scholars, 50,182. The general census gives the total number of children under ten years of age—boys, 52,996; girls, 53,082: and the total number under tuition at home or at school—boys, 17,990; girls, 17,271: leaving 70,817, inclusive of infants, not under any instruction.

Physical
character-
istics.

From its exposure to the North Sea, the climate of Norfolk is generally colder than other parts of England, and the prevalence of easterly winds in the spring retards the growth of vegetation to a later period than in the western districts. The surface of the country presents less variety than most of the other English counties, being generally flat, and uninteresting to the traveller in search of the picturesque. The coast is chiefly comprised of low sandy beach, seldom rising into bold elevations. The only lofty cliffs are St Edmund's Point at Hunstanton, and the chalk and clay cliffs at Cromer, which are fast yielding to the incursions of the ocean. The scenery is not woody; but of late years timber has been more generally planted, for use as well as ornament, than was formerly the case. The rivers, although slow and sluggish in their course, are easy of navigation, and, with the sea on the northern and eastern sides, form natural water-boundaries to this county, making it almost an island; in the eastern valleys the streams frequently expand into large *meres* or *broads* abounding with fish. The Great Ouse, navigable for barges 24 miles from its mouth, rises in Northamptonshire, enters this county at Downham, and enters the large estuary of the Wash, which divides Norfolk from Lincolnshire, near Lynn. It affords water communication with seven of the midland counties. The Little Ouse and the Waveney rise within ten feet of each other in the southern part of the county, but pursue directly opposite courses, forming the boundary line between Norfolk and Suffolk until the Little Ouse meets the Great Ouse on the borders of Cambridgeshire, and the Waveney, becoming navigable at Bungay, meets the Yare at Burgh, and falls into the sea at Yarmouth. The Bure rises near Aylsham, and, after receiving the Thurne and Ant, falls into the Yare, which rises near Attleburgh, becomes navigable at Norwich, and, after receiving the waters of the Tass and the Wensum, merges in the Waveney. A ship-canal has been cut across the marshes from Reedham to Lowestoft in Suffolk, connecting the Yare with the sea. The Nar rises near Litcham, and has a short course to the sea near Lynn, whence it is navigable to Narborough, a distance of sixteen miles.

Parlia-
mentary
divisions.

The Reform Act divided the county into two parts, East and West Norfolk, each returning two knights of the shire to Parliament. The eastern division comprises eighteen out of the thirty-three hundreds into which the county is divided, and its polling-places are Norwich, Yar-

mouth, Loddon, Long Stratton, Reepham, and North Walsham. West Norfolk comprises fifteen hundreds, and its polling-places are East Dereham, Fakenham, Lynn, Downham, Thetford, and Swaffham; the latter of which is the principal place of election.

The municipal boroughs and corporate towns of Norfolk, each also returning two members to Parliament, are—

	Inhabited Houses.	Population.
Norwich.....	14,988	68,195
Great Yarmouth, with Gorleston.....	6,886	30,879
King's Lynn.....	3,845	19,355
Thetford.....	844	4,075

The agriculture of this county is the foundation of its industrial prosperity. Few counties of England possess a greater variety of soils, and the peculiar excellence of the far-famed Norfolk agriculturist consists in the skill with which he *mixes* these various soils, thereby improving the *texture*, and therefore the productive qualities of all. By judicious claying and marling, large tracts of light sandy desert, moor, and heath have been converted into rich arable land; and by the extensive use of draining-mills, both wind and steam, the low marsh lands have been converted into rich valleys of fruitful corn-fields. Ten years ago it was said of the agriculturists of this county, that they knew as much as would be necessary, if known generally, to make England produce half as much again as it was at that time doing. The more general diffusion of agricultural science since that time may have lessened the comparative superiority of the Norfolk farmers, but, as they took the lead in throwing off the fetters of antiquated systems, they continue to preserve their character for adopting readily all hints for improvement, and still exhibit examples of the most judicious practices in husbandry. The ploughing and drilling here are excellent; even indifferent skill in these branches is very rare. The ploughs used are of light construction, drawn by two horses, or frequently bullocks, for which a peculiar breed of Devons are employed, and driven from behind with reins by the man who guides. This mode of driving is said to be the cause of the straightness of the lines preserved by both ploughs and drills. The most prevalent system of cropping now is the four-course, as first introduced by the late Earl of Leicester; and the usual rotation is, turnips, barley, clover or other grasses, and wheat. The five-course system is not uncommon, but the old six-course is very rare. Nearly all the corn is stacked in the field.

The number of farms in the county employing labourers is 4868; those not employing labourers, or not making returns, 1664—total, 6532. Number of labourers employed in the field—men, 32,840; women, 606—total, 33,446. Upwards of 200,000 acres of commons and sandy heaths have been inclosed during the last eighty years.

The average yield per acre¹ is ten cooms or five quarters of barley, and nine cooms or four and a half quarters of wheat. Above 1,045,760 acres of land are under cultivation. Its agricultural productions are chiefly wheat, barley, oats, peas, beans, potatoes, turnips, mangel-wurzel, beet, hay (composed of rye-grass, clover, suckling, trefoil, or sainfoin). Hemp is grown on the borders of Suffolk, and flax is cultivated for the sake of the linseed to fatten cattle, as well as for the flax itself. The management of the turnip crop is a point on which Norfolk agriculturists have long been pre-eminent. This valuable root was first introduced into field culture in the reign of George I. by Viscount Townshend, upon his estates in Norfolk. By the immense stock of winter food they supply, an enormous increase in the number of cattle and sheep bred and fattened in the county has been produced. The principal implements used in husbandry here are light ploughs, scarifiers, harrows, drills, horse-hoes, chaff-cutters, and threshing-machines. Wheat is often dibbled, the women and girls finding em-

¹ In 1831 the average yield of wheat was 3 quarters to the acre, showing an increase of 50 per cent. since that period.

Norfolk. ployment in dropping the seed. The quantity of grain exported from the various ports of the county before the opening of railways has been nearly 600,000 quarters in a year, but since that time the exports have much diminished. The principal market of the county is held at Norwich, for cattle, corn, and sheep. For the year ending October 1857, the amount of wheat brought to the Norwich market was 270,768 quarters, and of barley 187,245 quarters. The Norwich cattle-market is one of the largest in England; but the live stock of the county possess few distinctive characteristics. The principal cattle bred are Durhams or short-horns, but many Scotch and Irish are sent over to be grazed. Devons are used for ploughing, on account of their quicker step and activity. There are but few dairies, and these are confined to the neighbourhood of large towns. The indigenous breed of Norfolk sheep is now almost extinct, their hardy habits and agile movements, which were virtues when land was less cultivated, becoming defects when quickness of fattening became the primary quality requisite. The sheep now chiefly bred are Downs and half-bred Downs. The cart-horses are a fine breed, averaging from 14 to 15 hands high. Norfolk pigs are comparatively small; the finest now in the county are descended from the Berkshire boar and Chinese pigs. Poultry of all kinds is plentiful, and of a superior quality. The turkeys are most highly prized; vast quantities are sent to the London markets. No county is better stocked with game, especially pheasants and partridges, which are sedulously preserved by the landlords, and generally reserved in the leases. Great numbers of rabbits are bred in extensive warrens in many parts of the county.

From the earliest times Norfolk has been the seat of manufacturing operations. For four centuries it was the main centre of the woollen trade, first introduced by a colony of Dutch weavers, who crossed the Channel, and settled themselves at Worsted, a village about 13 miles from Norwich. The sumptuary laws of Edward III., and the fixing of staples at Norwich, tended to the increase of the manufactures; and the persecutions of the Duke of Alva, which drove large numbers of Dutch and other artisans to these shores, promoted the prosperity of the county. The most flourishing period of Norfolk woollen manufactures was during the middle of the last century. Bombazines, crapes, paramattas, and silk goods of every description, are now made. From the absence of coal and iron in the district, the manufacturers cannot compete with the north for cheapness, but for quality their goods are yet unrivalled. The number of wool-staplers and woollen manufacturers in Norfolk, returned in the last census, was 587; silk do., and dealers in silk, 2269; engaged in flax, 146; in cotton manufactures, 383; rope and hemp, 863. Besides silk and woollen manufactures, many other very important factories have sprung up; as shoes, soap, paper, brushes, bricks, tobacco, starch, mustard, oil-cake, and many varieties of artificial manures. The fishing trade of Yarmouth is an important branch of Norfolk commerce. The mackerel fishing alone is estimated to produce £16,000 a year, employing 90 boats and 870 men. The number of fishermen in the county is 1340; fishmongers, 329. The herring fishery employs 160 boats and 1300 men, besides those on shore, and produces 100,000 barrels yearly. Yarmouth has also extensive malting establishments.

Of various kinds of produce, the quantity sent by railways to all parts of the kingdom, and exported from Lynn, Wells, and Yarmouth, is very great.

Norfolk has railway communication with London *via* Cambridge and *via* Ipswich from Yarmouth and from Lynn; and with the north and north-west of England *via* Peterborough branch from Ely.

The public and turnpike roads of the county are better than in most parts of England, being generally raised higher

than the adjacent land, and well drained by trenches on either side.

Norfolk is in the diocese of Norwich, and in the archiepiscopal province of Canterbury. It is the head of the judicial circuit of Norfolk, which comprises five other counties. The military and maritime government of the county is vested in the same individual. The Earl of Leicester is the present lord-lieutenant, *custos rotulorum*, and vice-admiral. In the two first capacities he presides over the affairs of the county, has the control of the militia, and the appointment of deputy-lieutenants and magistrates. As vice-admiral of Norfolk he executes his authority under the Lord High Admiral of England. The mayors of Yarmouth and Lynn have admiralty jurisdiction on the rivers of their respective boroughs and ports. In 1839 a rural police, or constabulary force, was established in the county, consisting of a chief constable and 136 subordinates. The force has been at various times augmented; and in 1857 consisted of one chief constable, one deputy-constable, and 219 subordinates; the total cost of whose maintenance, inclusive of all expenses connected with stations, &c., was £15,511 for the year ending October 1857. A comparison of the statistics of crime gives 686 cases of detected felonies in 1854, and 237 cases of undetected felonies. In 1857 felonies detected were 600; undetected, 199. The families receiving titles from places in Norfolk are the Howards, dukes of Norfolk; the Gordons, earls of Norwich; Conways, earls of Yarmouth. Thetford confers the title of Viscount on the Fitzroys. The Townshends are viscounts of Raynham, and barons of King's Lynn. The De Greys are barons of Walsingham, the Nelsons barons of Hillsborough, the Howards are barons of Castle Rising, the Hobarts barons of Blickling, the Calthorpes are barons of Calthorpe, the Walpoles barons of Wolterton and Walpole, the Harbords are barons of Suffield, and the Wodehouses barons of Kimberley.

The most remarkable ancient mansions, some of which, however, exist but in ruins, are Blickling Hall, Caistor Hall, Oxburgh Hall, Winwall House, Stiffkey Hall, Baconsthorpe Hall, Hunstanton Hall, Scales Hall, Fincham Hall, Thorpe Hall, Wallington Hall, and Merton Hall; many of which exhibit the castellated character, though they do not appear to have been regularly fortified.

The principal country seats of noblemen and gentlemen are:—Beeston Hall, Sir J. H. Preston, Bart.; Blickling, Marquis of Lothian; Buckenham Tofts, Lord Ashburton; Castle Rising, Hon. F. G. Howard; Costessey Hall, Lord Stafford; Elmham Hall, Lord Sondes; Gunton House, Lord Suffield; Harling Hall, Lord Colborne; Haveringland, E. Fellowes, Esq., M.P.; Heydon Hall, W. E. L. Bulwer, Esq.; Hillington Hall, Sir W. T. H. B. Folkes, Bart.; Holkham, Earl of Leicester; Honingham, Lord Bayning; Houghton, Marquis Cholmondeley; Keswick Hall, Hudson Gurney, Esq.; Ketteringham, Sir J. P. Boileau; Kimberley, Lord Wodehouse; Kirby Cave, Lord Berners; Langley, Sir W. B. Proctor; Melton Constable, Lord Hastings; Merton Hall, Lord Walsingham; Oxburgh, Sir J. P. Bedingfeld, Bart.; Quiddenham, Earl of Albemarle; Raynham, Marquis of Townshend; Scottow, Sir T. H. E. Durrant, Bart.; Wolterton, Earl of Orford.

Norfolk possesses few of the more important Celtic remains common on the western coast of the island; but barrows with their contents, celts, spear-heads, beads, and other vestiges of the ruder times, are found scattered throughout the whole surface. Of the Roman period, Caistor, by Norwich, is an interesting relic: its walls and towers mark it for one of those permanent stations, known by the name of *Castra Hiberna*, and hardly to be found beyond the limits of Britain. Of summer camps, Brancaster, Castle Rising, and Tasburgh exhibit more or less perfect vestiges; while coins and urns, glass and pottery, tes-

Island.

tify in a variety of localities to the former presence of the Romans. Numerous traces of Danish, Saxon, and Norman times present themselves over the whole county, both ecclesiastical and civil. Thetford Castle is a remarkable specimen of a Roman fortification; and as a sacred Norman edifice Norwich cathedral has few rivals in England. Many parochial churches in the county also remain as specimens of the Norman style. Binham Priory, and parts of the Abbey of Walsingham, are specimens of early English architecture; as also are Yarmouth and other parish churches; while noble specimens of the decorated and perpendicular periods abound in every direction. Another leading feature of the antiquities of Norfolk are the painted roodloft screens and magnificent brasses. Among the most interesting remnants of civil and domestic architecture may be enumerated the castle at Castle Rising, the only known building of that description in the kingdom; Caistor and Oxburgh Halls; the walls of Norwich, Yarmouth, and Lynn; the ruins of the bishop's palace garden; and the gates of the Close, Norwich.

At the time of the Reformation Norfolk possessed no fewer than 123 monastic institutions, abbeys, priories, nunneries, colleges, and hospitals. Many were richly endowed. Some interesting ruins still remain in the county; and the general ecclesiastical architecture presents many curious and interesting specimens to the antiquary. Above 120 round towers remain in various parts. Flint is the prevailing material of which they are constructed, through the scarcity of stone in East Anglia. The tithes in most of the parishes of Norfolk have been commuted for fixed annual rents.

Among many other distinguished natives of the county we may enumerate Queen Anne Boleyn, born at Blickling; Archbishops Parker and Herring; Bishop Maltby; Lord Nelson; Dr Samuel Clarke; Sir Edward Coke; Porson; Sir Robert Walpole; Mrs Fry; Crome the artist; Lindley, Hooker, and Sir James Smith, botanists; Mrs Opie; General Wilson, the hero of Delhi. (s. s. m.)

NORFOLK, a town of the United States of North America, Virginia, on the north bank of the Elizabeth River, 32 miles from the sea, and 106 S.E. of Richmond. The site is low and flat; the streets are broad, but somewhat irregular, and lined with handsome houses of stone or brick. The City Hall is adorned in front with six granite columns, and has a dome 110 feet high; the Mechanics' Hall is a building in the Gothic, and the Military Academy in the Grecian style. There are fourteen churches, one of which has a spire 200 feet high, nine seminaries, two reading-rooms, three banks, an hospital, and an orphan asylum. The harbour is large, secure, easily entered, and defended by two forts. Norfolk is the principal commercial town in Virginia, and, along with Portsmouth, on the other side of the river, the chief naval station in the United States. Its trade is facilitated by the canal through the Dismal Swamp to the south, and communication is kept up with New York and Philadelphia by steamers. The shipping of the harbour, 30th June 1852, had a total tonnage of 7716 registered, and 14,448 licensed and enrolled. The number of vessels that entered in that year was 85, tonnage 20,778; those that cleared 129, tonnage 24,447. In the same year six vessels were admeasured, with a tonnage of 408. Pop. (1850) 14,326; (1853) about 16,000.

NORFOLK ISLAND is the largest of a group of islands in the South Pacific Ocean, consisting of Norfolk, Nepean, and Philip islands, together with several scattered islets, or rather bare rocks, called the Bird Islands; S. Lat. (of the settlement on the south of Norfolk Island) 29. 10., E. Long. 167. 58. It is 600 miles W.N.W. of Auckland, and 900 N.E. of Sydney. These islands appear to rise from the surface of a submarine table-land, which extends for 18 miles to the N. and 25 to the S. of the group, with an average breadth of 18 miles, and an area of nearly 1000 square miles. The depth of water over this tract is remark-

ably uniform, not varying more than five fathoms; and it rises abruptly about 1000 or 1200 feet from the bottom of the surrounding ocean. Philip Island is about $3\frac{1}{2}$ miles south of Norfolk Island, and is of basaltic formation, rising to the height of 900 feet at the south, and sloping towards the north. Its area is about 500 acres. Nepean Island, which is separated by a channel 800 yards wide from the largest of the group, is entirely of coralline structure, and has a height of about 50 feet from the sea, and an area of 12 acres. Norfolk Island itself is not quite 5 miles in length, with an average breadth of $2\frac{1}{2}$. Its area is about 8960 acres, and its general elevation is about 400 feet above the sea, while in the N.W. the double summit of Mount Pitt attains the height of 1050 feet. The surface is broken by numerous gullies with steeply-sloping sides, and through these flow several streams, two of which have formed, by the accumulation of soil between the sea and the hills, a narrow strip of level ground, on which the settlement stands. The soil, consisting of decomposed basalt, is everywhere extremely rich; even on the higher parts it is fertile, and in the valleys the vegetation is most luxuriant. The principal tree, the Norfolk Island pine, resembling in appearance the Norway spruce, grows on all parts of the island, and attains in some places a height of 200 feet, and a circumference of 30 feet. Maple, ironwood, a small species of palm called the Norfolk Island cabbage-tree, and a fern having a height of 40 feet and fronds 11 feet in length, also grow in abundance. The underwood of the forests consists chiefly of lemons and guavas; and many plants originally exotics now grow wild here. Bananas, yams, sweet potatoes, and arrow-root, though tropical plants, flourish on the island; and oranges, coffee, maize, and rye may be raised. The amount of land under cultivation on the 31st December 1852 was 16 acres of sweet potatoes, 40 of maize, and 2 of garden ground. All sorts of domestic poultry thrive here; and there are bees which produce excellent honey. There were, on the 31st December 1852, 30 horses, 721 horned cattle, 4140 sheep, and 125 swine; but a considerable number of these have since been removed. The climate is healthy, and the heat is tempered by the sea-breeze: the temperature is rarely below 65°. Excellent roads have been made across the island in various directions, and bridges across the streams; while extensive farm buildings of a solid nature have been erected in various places. Norfolk Island, originally uninhabited, was first visited by Captain Cook in 1774; and in 1787 it was colonized partly by convicts and partly by free-men from New South Wales; but in 1810 it was abandoned, and all the buildings were destroyed. In 1825 it was again used as a penal settlement, and occupied by fifty soldiers, six civilians, and fifty criminals; but this establishment was finally broken up in June 1856, when the inhabitants of Pitcairn's Island, the descendants of the mutineers of the *Bounty*, 194 in number, settled on this island. The origin and present condition of this small community are unique. Their whole stock of knowledge and instruction was derived from a common seaman, who was able to read and write, and being in possession of a Bible, undertook to teach the children of the original mutineers, of whom he was the last survivor. These people have thus grown up, living peacefully and happily, in obedience to the precepts of religion, but at the same time destitute, from want of experience, of the knowledge and skill of other civilized communities. They have a magistrate, two councillors, and a chaplain; and they are now under the authority of the governor of New South Wales. They are affectionate, simple, and unsuspecting; but are ignorant of the use of the plough, and of the most necessary trades.

NORICUM, a province of the Roman empire, corresponding to portions of Austria and Bavaria, was bounded

Noricum.

Noris.

on the N. by the Danube, on the W. by Vindelicæ and Rhætia, on the S. by Italy and Pannonia, and on the E. by Pannonia. Its name was probably derived from *Noreia*, the ancient capital. It was a mountainous country, traversed by the Alpes Noricæ and other ridges extending from east to west. The valleys between these chains were watered by the Dravus (*Drave*) and other tributaries of the Danube. Yet, on account of the numerous marshes and forests, the soil was not very fertile. The most noted products were mineral. Large quantities of iron were exported to supply the manufactories of arms in Northern Italy, Mæsia, and Pannonia; salt was abundant; and even gold, according to Polybius, as quoted by Strabo, was at one time found.

The country, though alleged to have been for a long time under the government of a king, was divided into several distinct tribes of Celtic origin. Of these the best known were the Norici, who were anciently called the Taurisci; and the Boii, who are said by Cæsar to have emigrated from Boiohemum about 85 B.C. But after the district had been conquered by the generals of Augustus about 13 B.C., the various tribes seem to have lost their individuality, and Noricum itself was reduced into the form of a Roman province. The face of the land also began to assume a new aspect. The fens were drained, the forests were cut down, the climate became milder, and the valleys waved with rich harvests. Several Roman roads traversed the country; and three Roman fleets on the Danube kept back the marauding barbarians of the north. Colonies also were founded, which in course of time became well known under the names of Celeia (*Cilly*), Virunum, Juvavum or Juvavia (*Salzburg*), Lauriacum (*Lorch*), and Boiodurum (*Innsbruck*).

NORIS, HENRY, a learned cardinal of the seventeenth century, was born at Verona in 1631. He was carefully educated by his father, Alexander Noris, originally from Ireland, and well known by his *Guerre di Germania*. At fifteen he was admitted as a boarder in the Jesuits' college at Rimini, where he studied philosophy; after which he applied himself to the writings of the fathers of the church, particularly those of St Augustine; and taking the habit in the convent of the Augustinian monks of Rimini, he in a short time distinguished himself amongst that fraternity by his erudition, inasmuch that, as soon as he had completed his novitiate, the general of the order sent for him to Rome, to give him an opportunity of improving himself in the more solid branches of learning. His constant course was to study fourteen hours a day; and this he continued till he became a cardinal. He began his *History of Pelagianism* at Rome at the age of twenty-six, and published it at Florence in 1673. To this work he added *An account of the schism of Aquileia, with a vindication of the books written by St Augustine against the Pelagians and Semi-Pelagians*. In the following year the Grand Duke of Tuscany invited him to that city, made him his chaplain, and appointed him professor of ecclesiastical history in the university of Pisa. His History procured the author great reputation, but called forth several antagonists, to whom he published proper answers. The dispute grew warm, and was carried repeatedly before the sovereign tribunal of the Inquisition, where it was examined with the utmost rigour, and the author dismissed without the least censure. In 1692 he was called to Rome by Innocent XII., who made him under-librarian of the Vatican. This post was a step to a cardinal's hat; his accusers therefore took fire afresh, and published several new pieces against him. Noris tried to remove these scruples in a work which appeared in 1695, under the title of *An Historical Dissertation concerning One of the Trinity that suffered in the flesh*. In 1695 his Holiness honoured him with the purple. On the death of Cardinal Casanati in 1700, he was made principal keeper

of the Vatican Library. He died at Rome in 1704. His works are characterized by great elegance and erudition; and were published at Verona, in 5 vols. folio, in 1729-30.

NORMANDY, an ancient province of France, bounded on the N. by the English Channel; E. by Picardy and the Isle of France; S. by Perche, Maine, and Brittany; and W. by the English Channel; had a length of about 150 miles, a breadth of 75, and an area of 10,534 square miles. It now comprises the departments of Seine-Inferieure, Eure, Calvados, Manche, and the greater part of Orne. Its ancient name was *Neustria*; but it was designated Normandy in A.D. 912, when it was conquered by the *Normen* under Rolf, the brother of the first Scandinavian Earl of Orkney.

NORRIS, JOHN, one of the most eminent of the English Platonists, was born at Collingborne-Kingston in Wiltshire, where his father was a clergyman, in 1657. With a view to the clerical profession, he was sent to Winchester school; and at the Michaelmas term of 1676 he entered Exeter College, Oxford. At school he was distinguished for his classical attainments, and at college for his enthusiastic study of philosophy. He soon exhausted the scientific knowledge then current at his university; and eager to explore the fountainhead of that stream of which the waters were so sweet, he began the study of Plato and Aristotle. It was in the groves of the Academy, however, rather than in the halls of the Lyceum, that the young speculator first found what he was in quest of. He graduated as a bachelor in arts in 1680, and having soon after obtained a fellowship in All-Souls' College, he was enabled still farther to indulge his preference for Plato and his divine dialogues. For a temper so melancholy and devout as Norris's seems to have been, the transition from his favourite philosophy to the mystic theology was at once easy and natural; and to heighten the facility still more, he had his attention arrested by the brilliant name of Father Malebranche, a philosopher at once Platonic in temper and Christian in spirit. The *Recherche de la Verité* was then read by all for its lofty eloquence, and studied by the few for the ingenuity of its metaphysics. Norris began an ardent admirer, and ended a zealous disciple of this charming idealist. Meanwhile little was known of this solitary thinker until he inaugurated his career as an author in 1682, in *The Picture of Love Unveiled*, a translation of the well-known *Effigies Amoris* of Robert Waryng. During the same year he published a translation from the Greek of *Hierocles upon the Golden Verses of Pythagoras*, a performance which he followed up by an original work in 1683, entitled *An Idea of Happiness*. Rejecting the common notion of "moral virtue," taught by the Stoics and Peripatetics, as incapable of making men happy in the highest sense, he adopted the more exalted idea of "divine virtue," as inculcated in the writings of Plato and the Pythagoreans. The former regulates the actions of common life; the latter engages in divine meditation and seraphic ecstasy. "He that has only the former," says Norris, "is like Moses, with much difficulty climbing up to the holy mount; but he that has the latter is like the same person conversing with God on the serene top of it, and shining with rays of anticipated glory." This small treatise at once ranked its author with that distinguished band of Platonic divines which adorned the seventeenth century in England. But it was a characteristic of Norris, as of all the thinkers of that devout and learned school, that while intensely fond of speculative retirement, and "happy in leisure and obscurity," as he sings of it, he nevertheless took an active interest in what was passing around him during that noisy and changeable time. The Rye-House plot of 1683 induced him to publish *A Murnival of Knaves, or Whiggism displayed and burlasqued out of countenance*; a performance which showed that its

Normandy
||
Norris.

Norris. author could discourse of more things than the ecstasies of the mystical union. This sturdy English sense has always proved too much for the full growth and fruition of the higher rhapsodies of mysticism. The political brochure hurled at the Whigs was followed by an attack upon the Calvinistic dissenters, in which the Fellow of All-Souls stanchly combated some of the positions in the theology of the Genevan divine. This tract was entitled *Tractatus adversus Reprobationis Absolutæ Decretum, novo methodo et succinctissimo compendio adornatus, et in duos libros digestus*, 1683. Nor was this the only blow aimed by the sturdy churchman at the dissenters of his day; in 1691 he charged the Nonconformists with schism in a special treatise, after having given them repeated stabs as a sort of by-play in his previous works. Norris obtained his master's degree in 1684, took orders shortly afterwards, and published his *Miscellanies* in prose and verse during the same year. In his poems he endeavours to be something "more than a country fiddler;" aspires "to restore the declining genius of poetry to its primitive and genuine greatness, to wind up the strings of the Muse's lyre," and so forth; and to save his readers from becoming oblivious of his high design, he informs them occasionally, as he proceeds, "this ode is after the Pindaric way." His argument is always high, however; and amidst much purity of sentiment, deep religious fervour, and some tedious moralizing, true gleams of poetry occasionally break forth. This volume was the most popular of all his works, and passed through numerous editions during the author's lifetime. Norris had long been an admiring student of the works of Dr Henry More, then at the height of his newly-won fame as a Platonic mystic, and he resolved now to consult that philosopher respecting some speculative difficulties on which he professed ignorance and curiosity. The correspondence thus begun in 1684 ended only with the death of More three years afterwards, and was published by Norris in 1688. In 1685 he produced a translation of Xenophon's *Cyropædia* in conjunction with Francis Digby, the latter rendering the first four books, and Norris the remaining four. *The Theory and Regulation of Love* appeared in 1688, in which that Platonic affection of which Norris was so fond finds an ingenious and eloquent advocate. He was made rector of Newton St Loe in Somersetshire in 1689, married during the same year, and gave to the world a treatise on *Reason and Religion*. This was followed, in 1690, by *Reflections upon the Conduct of Human Life*, in a letter to John Locke's friend, the famous Lady Masham. Locke was living with that lady at the time, and on reading Norris's dedication, in which he supposed her to be blind, is said to have "made himself merry withal" at the author's expense. Locke's celebrated *Essay* appeared for the first time during this year, and Norris, whose speculative opinions differed most fundamentally from those of Locke, could not resist the temptation of attaching an Appendix to his *Treatise of Christian Blessedness*, then passing through the press, with "Cursory Reflections upon a Book called *An Essay concerning Human Understanding*." His letter to Lady Masham brought him into collision with the Quakers, in *A Discourse concerning the Grossness of the Quaker's Notion of the Light within*, published in 1692, in which he disabused the minds of that pious sect of the opinion that he was favourable to their views. This treatise is peculiarly valuable, as casting light upon Norris's real relation to mysticism. He had before had occasion to denounce the opinion that all bodily pleasures are to be abjured, and he now insists, with great force and clearness, that "the Quakers represent this light within as a sort of extraordinary inspiration; whereas I suppose it to be a man's natural and ordinary way of understanding." Norris was now presented to the rectory of Bemerton, near Salisbury, where he remained till his death. The revenues of this

position were handsome and the work light; and the laborious rector continued to ply his pen with increased ardour. He completed his four volumes of *Practical Discourses* in 1698, and his *Letters concerning the Love of God*, addressed to Mrs Astell, appeared in 1695. The subtle mystical tendencies of the writer's mind come forth in the latter work with peculiar distinctness. He exalts sentiment above science, and feeling above reason. He insists on the absolute exclusiveness of the love of God, and its incompatibility with any possible earthly affection as an end in itself. These opinions he had afterwards occasion to re-assert and vindicate. A very able work from Norris's pen, entitled *An Account of Reason and Faith, in relation to the Mysteries of Christianity*, appeared in 1697, in answer to the *Christianity not Mystical* of the deistical writer John Toland. Perhaps none of the author's writings would be read with so much interest at the present day as this one. His discussion of the grounds and merits of the rationalism of that period was so thoroughgoing, that the more modern forms of doubt are in a great measure anticipated. None of our modern writers have marked off with a more bold and steady hand the respective provinces of Reason and Faith, whether in the region of natural or supernatural truth. And a truly earnest inquirer, with any adequate appreciation of the real significance of sound speculation, will find more satisfaction in Norris's book—now all but forgotten—than in nine-tenths of all the treatises, pretentious and otherwise, addressed to the thinking public of the present day. The human Reason, according to Norris, is not co-extensive with absolute truth, and Faith occupies the border-land between the known and the unknown, the hidden and the revealed. Each faculty has accordingly a legitimate and inalienable sphere of its own, which can only be usurped at the peril of intellectual and moral disorganization. The work, however, by which Norris is best known to the philosophical world is one of less real merit than the former, but occupied with a subject of capital interest to all metaphysicians. He was one of the very first, as has already been observed, to raise his protest against the apparent sensationalism of Locke; and after meditating the subject for seven years, Norris came before the public in 1701 with an elaborate defence of idealism, in *An Essay towards the Theory of the Ideal or Intelligible World*. The second part appeared in 1704. This work is in effect a defence and development of the philosophy of Malebranche, whom Norris styles "the great Galileo of the intellectual world." It displays wide reading and vigorous thinking, and is written in a clear, forcible style. His next work was *A Philosophical Discourse concerning the Natural Immortality of the Soul*, published in 1708, defending that doctrine, with great ability and moderation, against the hostile criticism of Dodwell. With the exception of small treatises on *Humility* (1707) and *Christian Prudence* (1710), and other minor pieces on practical subjects, this work may be regarded as the last of this industrious and able writer. His health, which had never been very robust, ultimately gave way under the ceaseless pressure of active labour; and after lingering for some time, he died at Bemerton in 1711, at the age of fifty-four.

NORRISTOWN, a town of the United States of North America, state of Pennsylvania, stands on an elevated spot on the left bank of the Schuylkill, 91 miles E. of Harrisburg, and 17 N.W. of Philadelphia. It is regularly laid out, and well built of stone and brick. There is a handsome court-house, begun in 1851, of light-gray marble; a prison, a bank, a public library, nine or ten churches, and several large boarding-schools. The river, which is here crossed by two bridges, supplies moving power for two large cotton factories and other manufacturing establishments, which employ a great number of hands. The trade of the place is considerable, and is increased by the naviga-

North. tion of the river, and by railways extending to Philadelphia on either side of it. Pop. (1850) 6024.

NORTH, Sir DUDLEY, styled by Macaulay "one of the ablest men of his time," was the third surviving son of Lord North, Baron of Kirtling, and was born on the 16th May 1641. He received at Bury and at a writing school in London an education which fitted him for a mercantile life. Being then bound to a Turkey merchant, he was soon afterwards sent out to Smyrna as a factor. The young trader began his career with a scantily-stocked warehouse, but with a determination to make a fortune which might enable him to close his days in ease and luxury at home. Though naturally fond of frolic and pleasure, he kept himself apart from profligate companions, lived with the most careful thrift, and turned all the faculties of his powerful mind upon the duties of his calling. But it was not until in course of time he had been engaged to take the management of an embarrassed factory at Constantinople that he obtained any prospect of success. After collecting the debts of his employer, he established himself in a factory of his own, and began to achieve success by an artful system of policy. He sought the acquaintance of the various foreign ambassadors at Constantinople; he did not hesitate to conciliate the Turks by accommodating his conduct to their superstitions; and he employed all the stratagems of trade with an ability which the most wily Jew could not overreach. The result was, that in 1680 the great object of his life had been gained, and he was on his way home to England. Dudley North had not been long settled in London when his profound knowledge both of the theory and practice of commerce was the means of introducing him into public notice. He was advanced to the office of sheriff, and proved himself a most efficient and unscrupulous tool of the dominant Tory faction. His services were rewarded with a knighthood, an alderman's gown, and the post of a commissioner of the customs. Returned to Parliament for Banbury in 1685, he rendered himself unfavourably distinguished by proposing and carrying a tax on sugar and tobacco. But the most permanent cause of his reputation was the publication, in 1691, of his *Discourses on Trade*, a work which is said by Mr McCulloch to contain "a much more able statement of the true principles of commerce than any that had then appeared." The author died on the 31st December of the same year.

NORTH, Francis, Baron Guildford, Lord Keeper of the Great Seal, was the elder brother of the preceding, and was born on the 22d October 1637. From the school of Bury he passed, in 1653, to St John's College, Cambridge, and after studying there for two years as a fellow commoner, he became a member of the Middle Temple. Young North began his legal career with all that concentration of purpose which distinguished his family. His volatile disposition and his passion for pleasure were kept in check; and, setting himself doggedly to the study of law, he endeavoured to subject all his propensities to the calm control of self-interest. The same line of policy was pursued when he had been called to the bar in 1661, and began to travel the circuit. No kind of influence was thought too insignificant to be won. He truckled to the prejudices of the judges; fawned upon those whose hands were full of briefs; and sometimes chose to ride and starve with a certain miserly serjeant named Earl, in order that he might draw from the large experience of his fellow-traveller an account of all the tricks and subtleties of law. By such means the time-serving aspirant soon acquired a proficiency and reputation which combined to lead him on to the highest legal preferments. He was appointed solicitor-general in 1671, attorney-general in 1673, and lord chief justice of the Common Pleas in 1675. At length, in 1682, the Great Seal was intrusted to his keeping. In

this high position, where he was the object of general attention, and at this time, when the political world was torn into two factions, North stood prominently out as the most temporizing of the Trimmers. With that low species of tact which cowardice supplies, he shunned every occasion and every company where he might be betrayed into an express statement of his political creed. The letter of the law was the moral code by which he justified his public conduct, and allegiance to the sovereign was the virtue with which he covered his private bearing. It was only when he was sinking into the grave amid general neglect and distrust, that he first showed courage, by warning the infatuated James II. of the ruin towards which the government was tending. His death took place on the 5th September 1685.

The Lives of Dudley and Francis North, and of Dr John North, a younger son of the same family, written by their brother Roger North, were published in 2 vols. 4to, 1740-42, and republished in 3 vols., London, 1826. The biographer, although a partial, self-conceited gossip, and a bigoted Tory, unconsciously blabs out now and then many little circumstances which silently cancel his absurd eulogies, and exhibit his heroes in their real characters. (See also Campbell's *Lives of the Chancellors*, and Macaulay's *History of England*.)

NORTH, Frederick, Earl of Guildford, the favourite minister of George III., was of the same family as the preceding, and was born on the 18th April 1733. After receiving his education at Eton, and at Trinity College, Oxford, he resided for some time on the Continent preparing himself for his future career. An early entrance into Parliament was followed by a gradual rise through several cabinet offices, until in 1769 he became chancellor of the exchequer, and leader of the House of Commons, under the ministry of the Duke of Grafton. His success in this high position soon proved that he was a proficient in parliamentary strategy. Accordingly, on the resignation in 1770 of the nobleman at the head of the ministry, he was requested to assume the vacant office. The readiness with which North obeyed the request, and relieved the embarrassed mind of the king, made him a great favourite with George III., as he was already with the House of Commons. Yet the administration so auspiciously begun soon became remarkable for the calamities it brought upon the nation, and the strong and malignant opposition it excited. The refusal of the ministry to relieve the American colonists from the paltry duty on tea, led to disturbances in 1773 which issued in open rebellion in 1775. Then the Whig Opposition, led on by Burke and Fox, commenced a series of the most virulent attacks that had ever been witnessed in the British senate-house. Not content with execrating the public policy of the minister, they blackened his private character, cast taunts upon his capacity, raked up every family scandal, and even clamoured for his head. The Parliament hall resounded with the most confused and boisterous wrangling. Yet on many a stormy night Lord North fought almost single-handed against his great adversaries, meeting their bold measures with his consummate tact, counteracting the effect of their grand rhetorical displays with his strong common sense, and blunting the edge of their satire with his pungent wit and imperturbable good humour. For six years he thus kept his ground triumphantly. By that time, however, affairs were beginning to draw towards a crisis. The British were shamefully falling in their attempts to suppress the Americans; France and Spain had espoused the cause of the colonists; the public were waxing loud in their indignation against the ministry; and in 1781 William Pitt, entering Parliament, consummated the oratorical strength of the Opposition. Lord North, though he still held his original opinion regarding the justice of the American war, would then willingly have resigned. But he was repeatedly induced

North.

Northallerton
||
Northampton.

by the opinionative king to pursue, in opposition to his inclination, that administration which was endangering the safety of the country. At length, in 1782, he was forced to give place to Lord Rockingham. The rest of the parliamentary career of Lord North did not retrieve his political reputation. Though the celebrated coalition which he formed with Fox overthrew the ministry of Lord Shelburne and Pitt, and raised him in 1783 to the post of secretary of state under the Duke of Portland, yet it became universally unpopular, and did not keep him in power for more than six months. This was the last time that North was in office. He died in 1792, five years after he had been struck with blindness, and two years after he had succeeded to the family estates and to the title of the Earl of Guildford. (For fuller information regarding the administration of Lord North, see *BRITAIN*. See also Lord Brougham's *Statesmen of the Time of George III.*)

NORTHALLERTON, a parliamentary borough and market-town of England, capital of the North Riding of Yorkshire, on an affluent of the Whisk, 32 miles N.N.W. of York, and 225 N.N.W. of London. It consists of a principal street, broad and well paved, and numerous lanes diverging from it. The parish church is large, in the form of a cross, and has a square tower at the west end. There are also chapels belonging to Independents, Wesleyans, and Primitive Methodists, Baptists, and Quakers; and several schools and charitable institutions. One of the latter, called the *Maison Dieu*, was founded in 1476, and has since been rebuilt. Northallerton has a market-house near the centre of the town, a jail built after the plan of Howard, and a court-house. There are here flour-mills, tanneries, brick-kilns, breweries, malt-houses, and other manufactories. The market-day is Wednesday; and five yearly fairs are held. In the neighbourhood of the town is a place called *Standard Hill*, where was fought, in 1138, the battle of the *Standard*, in which King David of Scotland was defeated by the English. The borough of Northallerton returns one member to Parliament. Pop. (1851) 4995.

NORTHAMPTON, a parliamentary and municipal borough and market-town of England, standing on the north side of the River Nen or Nene, is probably the *Antona* of Tacitus (*Annal.* xii. 31); Lat. 52. 15. N., Long. 0. 55. W., 67½ miles from London by the London and North-Western Railway. It is a place of great antiquity, and supposed to have been of British origin; but the earliest mention of it is in the Saxon Chronicle, under the name of *Hampton*: in *Domesday Book* it is called *Northantone*. The castle, of which only some small portion of the walls and an arch of semi-Norman character remain, was built by Simon de St Liz, to whom William the Conqueror had given the town with the hundred of Fawsly. Several Parliaments were held here; the first of these in 1130–31, in the thirty-first year of Henry I.; and the last, in the fourth of Richard II. (1380), being that which originated the poll-tax that occasioned the rebellion of Wat Tyler and Jack Straw. From its central situation, the town or its neighbourhood was frequently the scene of conflict during the civil wars both of earlier and later date. On July 10, 1460, a battle was fought here between Henry VI. and the Yorkists, &c., when the former was defeated, and brought a prisoner into the town. In 1642 Northampton received a garrison for the Parliament under Lord Brooke. On March 30, 1645, Cromwell marched from it with 1500 horse and two regiments of foot to Rugby. After the Restoration, October 17, 1661, the walls of Northampton, with those of Coventry, Leicester, Gloucester, and Taunton, were demolished, these towns having taken the side of the Parliament. In 1675 the town was almost destroyed by a fire in the short space of six hours; £25,000 was collected by briefs and private charity towards repair-

ing the damage. Charles II. gave 1000 tons of timber from Whittlewood Forest towards rebuilding All Saints' church, and remitted the duty of chimney-money for seven years. In 1720 it was damaged by an extraordinary flood. In 1750 a violent shock of an earthquake was felt, which lasted nearly a minute; and in 1776 another of shorter duration.

The town is pleasantly situated on an eminence sloping to the south. Its general appearance is neat and clean. The older buildings are constructed of a brownish-yellow stone found in the neighbourhood, being the inferior oolite; the modern houses are chiefly of brick or of a white stone (the great oolite) from quarries in the adjacent village of Kingshorpe. The general style of architecture has nothing remarkable: numerous alterations of late years have been going on, chiefly in making more showy frontages to the shops. The market-square is one of the largest in the country, being about 600 feet square. For the last twenty years the town has been rapidly extending, especially towards the N. and E.: on the outskirts a great number of new streets have been built, consisting of neat tenements adapted to the working-classes, which form a pleasing contrast to those built at the commencement of the century. On the eastern side houses and villas of a more imposing aspect have been erected for the use of the gentry and more opulent tradesmen. The streets in general are well paved, and lighted with gas.

Of the public buildings, the principal are—the general infirmary, established in 1747; the present building was erected in 1793, and affords accommodation for about 120 patients. It has a medical library of 3000 volumes, and a splendid collection of anatomical casts, which are deposited in a separate building, containing also a convalescent ward for ten male and ten female patients. The general lunatic asylum, about half a mile from the town in the same direction as the infirmary, was opened in 1838, and by subsequent enlargements is able at the present time (1858) to receive about 280 patients. It is a self-supporting institution. The Royal Victoria Dispensary, established in 1844 to commemorate the visit of her present Majesty to the town, is conducted on the provident principle, every member above the age of fourteen subscribing one penny per week: twopence a week will admit a man and his wife and all his children under fourteen years old. The union workhouse, on the Wellingborough road, has accommodation for 300 inmates. The county-hall, where the quarter sessions, the assizes, and county courts are held, is a good specimen of Italian architecture, contemporary with the later features of All Saints' church. The town-hall is an ancient building, and retains a good deal of carved paneling from the time of Henry VII. to that of Elizabeth. Forty or fifty years ago alterations were made which diminished the original capacity of the principal storey; and the external staircase, which previously existed, was removed, and one within the building substituted. As it now stands, it is very inadequate to the wants of the town. The corn exchange, erected a few years ago, consists of one large hall, the interior of which has an imposing effect; it is frequently used for musical performances, and has an excellent organ; attached to it are the offices of the mechanics' institute, which has a library of nearly 11,000 volumes, and now enrolls 600 members. The Religious and Useful Knowledge Society, supported principally by members of the Established Church, occupies a building in another part of the town. It has about 1000 members.

The town has seven churches—All Saints', St Sepulchre's, St Peter's, St Andrew's, St Katherine's, and St Edmund's. The last three are of recent date. The old church of All Saints, which was considerably larger than its successor, was destroyed by the great fire of 1675; but the tower escaped, and was incorporated with the new

Northampton.

Northamp-
ton.

structure. Its style is the decorated, and the additions, in defiance of all congruity, are in that Italian style which Inigo Jones and Wren had rendered fashionable, and, as such, have great merit. The interior of the church is strikingly beautiful. It contains a statue, by Chantrey, of Spencer Percival, many years a member for the borough. At the western entrance a portico extends the whole width of the church, consisting of twelve Ionic pillars supporting an entablature and balustrades. A statue of King Charles II. surmounts the centre; he is represented in Roman costume, with a truncheon in his hand, and his head covered with a wig of ample curls. St Peter's is a most interesting specimen of early and richly-ornamented Norman work. The capitals of the columns of the nave are charged with curious sculptures in a high state of preservation. The tower arch also is elaborate, with chevron mouldings; and some pilaster columns, on each side, are richly ornamented. Externally, also, the church has many interesting features; the tower especially, which has buttresses of three semi-columns diminishing at each storey. St Sepulchre's has a special interest as one of the four existing round churches built after the model of the Holy Sepulchre at Jerusalem. It bears evidence of having been erected at periods widely different: the circular part is Norman and early English; the spire, a fine piece of work, is perpendicular. St Giles' has a good Norman door at the western entrance, and the tower arch is of the same period.

Of the places of worship belonging to the various non-conformist bodies, four belong to the Baptists; five to the Wesleyan, Primitive, and Associated Methodists; three to the Independents; the Unitarians, Quakers, and Roman Catholics have one each. In Castle Hill Chapel, a mural tablet is erected to the memory of Dr Doddridge, who exercised his ministry there for upwards of twenty years. A similar memorial is erected in the Baptist chapel in College Street to the memory of the Rev. John Ryland, who was minister there for thirty years, and was succeeded by his son, the late Dr Ryland, afterwards president of the Bristol Baptist College.

St John's Hospital, in Bridge Street, is a very ancient, and was at some period a very wealthy foundation. Its available revenues are now equal only to the maintenance of a certain number of aged women, some of whom have rooms in the building. The importance of the charity in early times is evident from the architectural features of the hospital still remaining. St Thomas's Hospital was founded in 1450, in honour of St Thomas à Becket. It was first endowed for twelve poor widows; to these six were added by Sir John Langham in 1684, and since then the numbers have been still further increased.

In Mafare is the free grammar school, founded in 1556 by Thomas Chipsey, a grocer of the town. Dr Thomas Cartwright, Bishop of Chester, and James Hervey, the author of the *Meditations* and other works, were educated here. A free school, called the Blue-Coat School, was founded in 1700. There are also various parochial schools, and an excellent British school for boys and girls. The Sunday schools belonging to the Established Church and the different bodies of dissenters are numerous.

The town is divided into three wards—east, west, and south; and is governed by a mayor, six aldermen, and eighteen councillors; besides nine justices of the peace, a recorder, and town-clerk. The borough has sent two members to Parliament from the commencement of the reign of Edward I.

The coach-road to the metropolis, through Newport-Pagnell, Woburn, Dunstable, St Albans, and Barnet, has been superseded by the London and North-Western Railway, which is connected with Northampton by means of a branch line from Blisworth, making the distance 67½ miles. From Northampton the railway has been carried

Northamp-
ton.

eastward to Peterborough, and a line, entering the town at the West Bridge, is also now in progress from Market-Harborough, where it will join the line from Leicester to Hitchin. Before the formation of railways, coals and heavy goods were brought to Northampton by means of the Nen and a branch canal from the Grand Junction at Blisworth. Markets for the supply of meat and vegetables are kept on Wednesdays and Saturdays; the latter is also a cattle-market. About twelve fairs are held in the course of the year. That on September 19 is called the "cheese fair." The wool fair is held in the first week in July. The race-course is 117 acres in extent. The Northampton and Pytchley Hunt races are held in March, at the close of the hunting season.

The barracks were finished in 1796 for the accommodation of cavalry, and are situated at a short distance from the race-course.

The borough gaol was opened in 1846. It is constructed on the separate system, and is capable of containing eighty persons. The county gaol was opened in the same year, and is capable of receiving 150 prisoners. About a mile S. of the town, on the old London road, is one of the crosses erected by Edward I. to the memory of his queen, Eleanor of Navarre. It is a work of great beauty, and in fair preservation, but the upper portion has long been wanting, and no record remains of its character. An entry in the expense rolls makes mention of five images, and it has been conjectured that the fifth (only four being required for the canopy) surmounted the monument.

The staple manufactory of the town is that of shoes, in which the great majority of the working-classes are engaged. A large proportion of the army contracts are executed here and in the adjacent town of Wellingborough. Stockings were formerly made here; and the first stocking-frame used in Leicester was brought to that town in 1680 by a person from Northampton named Alsop. Lace-making also was carried on to some extent, but it has almost entirely ceased. There are three extensive iron-foundries in Northampton. At Rushmills, about 2 miles from the town, is a paper manufactory which supplies the bank-note paper and the stamps for postage. The population has rapidly increased during the last fifty years. In 1801 it amounted to 7220; in 1811 to 8427; in 1821 to 10,844; in 1831 to 15,351; in 1841 to 21,242; and in 1851 to 26,657. (J. E. R.)

NORTHAMPTON, a post-town and shire-town of Hampshire county, Massachusetts, one of the United States of North America. It stands on a hill near the west bank of the Connecticut River, 95 miles W. from Boston; and consists chiefly of two streets laid out with considerable regularity. It contains several handsome public buildings, of which the court-house, jail, and one of the churches are the most conspicuous. The private houses are in general large and in a good style, and many of them are elegant. Northampton is one of the most beautiful towns in New England, and distinguished for the refinement and intelligence of its inhabitants. A stream passes near the centre of the town, on which are erected numerous mills and many manufactories. The rearing of the silk-worm has been carried on here for some time, and large quantities of silk, as well as cotton and woollen goods, are manufactured. Farmington Canal extends from Newhaven to this place. A bridge, built in 1826, connecting this town and Hadley, is 1086 feet in length by 36 in breadth, and is supported by six piers and two abutments. The lands bordering on Connecticut River, in which are now the towns of Northampton, Hadley, and Hatfield, were first known by the Indian name *Nonotuck*. It was the third place settled on the river in this state, and was incorporated in 1654. Amongst the striking objects in the scenery of Northampton are the

Northamptonshire. beautiful river, and the heights called Mount Tom and Mount Holyoke, the former being 1200 and the latter 900 feet above the river. Long. 72. 38. W., Lat. 42. 19. N. Pop. (1850) 5278.

NORTHAMPTONSHIRE, one of the midland counties of England, bounded by a greater number of counties than any other like division of England, having on the N. the counties of Leicester, Rutland, and Lincoln; E. those of Cambridge, Huntingdon, and Bedford; S. those of Buckingham and Oxford; and W. Warwickshire. It lies between 51. 59. and 52. 40. N. Lat., and 0. 8. and 1. 20. W. Long. It is about 66 miles in length; the breadth in the widest part is 26 miles, in the narrowest not more than 8 miles. Its extent is 630,358 acres, of which probably 580,000 are arable, pasture, and meadow land. In 1841 the population was 139,228; in 1851 it had increased to 212,380, occupying 43,942 houses.

In ancient British times this county was the most southern part of the Coritani; by the Romans it was included in the province of Flavia Cæsariensis. The Roman roads Watling Street and Ermine pass through it; the former on the S.W. from Towcester to Lilbourne, the latter enters by Castor, and branches off at Upton. In the Saxon period this county made part of the kingdom of Mercia. It suffered repeatedly and severely from the incursions of the Danes. Simon De St Liz, a follower of William the Conqueror, having received from his sovereign the town of Northampton to find shoes for his horses, fortified it, and built the castle at the west entrance. During the 12th century many councils were held at Northampton. The battle which decided the fate of Charles I. was fought at Naseby, June 14, 1645. Besides an obelisk erected a mile to the east of the scene of action, the "Sulby hedges" still remain as a more exact landmark.

The whole of the county is within the diocese of Peterborough, with the exception of three parishes, Gretton, Nasington, and King's Sutton, which are in the diocese of Lincoln. It forms an archdeaconry, containing 293 parishes, of which 172 are rectories, 93 vicarages, and 29 perpetual curacies.

From the census of 1851, it appears that in this county there were at that time 592 places of worship, having in all 151,687 sittings. Of these, 292 places of worship belonged to the Episcopalians, 122 to various bodies of Methodists, 87 to Baptists, 56 to Independents, 6 to Quakers, 6 to Roman Catholics, 4 to Latter-day Saints, 3 to Moravians, and 16 to other bodies. The number of Sunday-schools was 426, with 33,614 scholars. Of the former, 257 belonged to the Episcopalians, 68 to Methodists, 52 to Baptists, and 39 to Independents. Of day-schools there were 276 public, with 18,969 scholars; and 411 private, with 7555 scholars. Of the public schools, 169 were supported by religious bodies, 88 by endowments, and 14 by general or local taxation. There were also 15 evening schools for adults, and 8 literary and scientific institutions.

By the Reform Bill the county was divided into two divisions, N. and S., each containing ten hundreds, and returning two members. The election for the northern division is held at Kettering, and the polling-places are Kettering, Peterborough, Oundle, Wellingborough, and Clipstone. The election for the southern is held at Northampton, and the other polling-places are Daventry, Towcester, and Brackley. Two members are also returned for Peterborough, and two for Northampton.

This county, although destitute of any bold or striking scenery, presents an agreeable variety of hill and dale, bearing those marks of cultivation which indicate industry and comfort on the part of the occupiers. The general elevation of the land is about 300 feet above the level of the sea; and the highest point, Arbury Hill, in the neighbourhood of Daventry, rises only to the height of 804 feet above sea-level. Owing to this absence of elevations, and to the

inland position of the county, it is less subject to heavy and continued rains than most parts of England. The climate is mild and salubrious; and the soil is generally rich and fertile. It is pretty equally divided for the purposes of tillage and grazing. Some of the farmers are great cattle-breeders, but the majority purchase beasts to fatten them for the market. Another agreeable feature is the great number of noblemen's seats, and the mansions of the gentry, with the parks and plantations that adorn them. The woodlands are extensive, consisting chiefly of the remains of the royal forests of Rockingham, Salcey, and Whittlebury, with the chases of Geddington and Yardley. The ash is the staple timber tree of the county, and fetches a high price.

The county is not remarkable for mineral productions. Limestone is abundant, and within the last few years the soil has been worked for ironstone in the neighbourhood of Northampton and along the line of the Peterborough Railway, and has been found to yield a tolerably large percentage. Good clay for bricks and tiles is to be met with in many parts: there are also quarries for roofing-slates.

The only navigable river in this county is the Nen, or Nene. It rises in the western part, flows across the county, and then runs N. till it enters the German Ocean by Lincolnshire. The Welland rises at Sibbertoft, and forms a boundary between the county and Leicestershire and Rutland. The other rivers, the Ouse, the Avon, the Severn, and the Charwell, which, like the two former, have their sources in Northamptonshire, are but inconsiderable rivulets till they enter the adjoining counties. Previous to the construction of railways the canals were important aids to inland traffic. The Oxford Canal connects the county with that city. The Grand Junction Canal, communicating on the one hand with London, and on the other with Liverpool and Manchester, passes through the county, and is navigable for barges of 60 tons burden. The Grand Union Canal connects it with Leicester.

At the period of the Reformation the number of religious houses, including colleges and hospitals, amounted to nearly sixty. Of the great abbeys, Peterborough is the only one that has been preserved entire; to which may be added the collegiate churches of Fotheringhay, Higham-Ferrers, and Irthlingborough. The principal monastic remains are to be found at Daventry, Canons' Ashby, and Dingley. The county is rich in almost every style of ecclesiastical architecture. As specimens of the early Norman style may be mentioned the churches at Earl's Barton, Barnack, Brixworth, Brigstock, Castor, Spratton, Barnwell, and Twywell. Of ancient mansions the most deserving of notice are Castle-Ashby, the seat of the Marquis of Northampton, of which the oldest part was built in the reign of Henry VIII.; and Burghley House, near Stamford, built by Queen Elizabeth's lord treasurer, and now the seat of the Marquis of Exeter. Kirby Hall, near Rockingham, built by Sir Christopher Hatton, is now falling rapidly to decay, though habitable within the last half century. Althorpe, the seat of Earl Spencer, of uncertain date, but restored by the Earl of Sunderland in 1688, claims notice for its magnificent library, formed principally by the grandfather of the present Earl (1858), being the richest in early printed works of any private collection in the world. Of the crosses erected by Edward I. in memory of his queen Eleanor which still remain, two out of three are in this county—one at Hardingstone, near Northampton, and the other at Geddington.

Of celebrated persons, who were natives of this county or connected with it, the following may be mentioned:—Robert Brown, founder of the sect of the Independents, born at Tolthorp, in Rutlandshire; John Dryden and Thomas Fuller, born at Aldwinckle; James Hervey, author of the *Meditations*, born at Hardingstone, and died at

North Cape Weston Favell; Bishop Wilkins; William Law, author of *The Serious Call*, born at King's Cliffe; Dr Doddridge, born in London, but resident at Northampton, minister of the Castle-Hill Meeting-House, and tutor of the Dissenting Academy in that town; Parkhurst, the biblical lexicographer; Dr Paley; and Dr Carey, the missionary and oriental scholar, born at Paulerspury. Two of America's greatest sons were connected with this county. Franklin's ancestors had a freehold estate of about 80 acres for at least 300 years at Ecton, five miles from Northampton, where they carried on the trade of blacksmiths. General Washington was the great-grandson of John Washington, of Sulgrave, who emigrated to America in 1637, and whose great-grandfather, Lawrence Washington, was mayor of Northampton in 1532 and 1548. At Northborough Oliver Cromwell's wife died, and his favourite daughter, Elizabeth, married Sir John Claypole, the lord of the manor, the chapel of whose family remains attached to the parish church. At Abington, Shakspeare's favourite grand-daughter, who married Sir John Bernard, lived and lies buried there. It would be unpardonable to omit the name of the late George Baker, whose *History and Antiquities* of the county form a monument of the indefatigable researches and minute accuracy of the author; and which his sister, Miss Baker, his faithful companion and fellow-labourer, by her ample *Glossary of Northamptonshire* (London, 1854) has made a lasting contribution to the history of our language. (J. E. R.)

NORTH CAPE, the most northerly point of Europe, is situated in the island of Magerøe, separated from Norway by a narrow strait; N. Lat. 71. 10., E. Long. 25. 46. It consists of a long range of steep rocks, about three-quarters of a mile broad, and 1200 feet above the sea. The geological structure of these rocks consists of gneiss, quartz, and other primary formations. On the E. side there is a small bay, hollowed out of the rock, which affords a landing-place; but at all other parts it is inaccessible from the sea.

NORTHCOTE, JAMES, an eminent English painter and writer on art, was the son of a poor watchmaker, and was born at Plymouth on the 22d October 1746. After receiving a scanty education, he was apprenticed at an early age to the trade of his father. He soon betrayed a decided love for painting, however, and some humble successes in portraiture induced him, after he had reached his twenty-first year, to abandon watchmaking, and to set up a small studio in his father's house. The chief event which determined the success of his after career was his introduction to Sir Joshua Reynolds in 1771, who received the young aspirant into his own house as one of his pupils. Northcote now entered upon a course of regular study, with an untiring enthusiasm which secured the approval and lasting kindness of his master. Late and early he was found either in the gallery of Sir Joshua or in the Royal Academy. At the expiry of his term of five years, the desire to look upon the great paintings of Italy occupied his mind. During the next year he plied his pencil in order to obtain money for his travelling expenses; and in 1777 he repaired to Rome, with a scanty purse and with no knowledge of any language except his own. It was his purpose to make portraits the staple of his support, and to devote his leisure moments to the higher and more congenial subjects of historical painting. Accordingly, during his sojourn of three years in Italy, the works of Titian and Michael Angelo were the chief objects of his study; and he flattered himself that he had caught the grand style of these great masters. Yet no sooner had he been removed from the daily inspection of Italian art, than he slid insensibly into an imitation of Sir Joshua Reynolds.

On his return to London in 1780, Northcote became a professional painter of portraits and history. An air of propriety pervaded whatever he executed; his colouring, some-

what dull, and his drawing, stiff and defective, were redeemed by a certain academic grace; and although he lacked the highest gift of an historical artist—the power of conceiving an entire scene in all its details—his knowledge of what a picture ought to be enabled him, after much careful correction and elaboration, to portray an event with feeling and clearness. A love of money combined with a love of art to keep him constantly before his easel. If his merits were not always recognised, it was not because he was too modest to display and avow them; and if his rivals sometimes threw him into the shade, it was because his contemptuous taunts and depreciating criticism failed to prevent them from rising. His services were soon hired by Alderman Boydell, a munificent patron of the fine arts, and the originator of "The Shakspeare Gallery." Northcote was thus enabled to concentrate all his attention upon that branch of the art most congenial to his taste. The first paintings that he executed for his employer were, "The Murder of the Royal Children in the Tower," "The Death of Wat Tyler," and "Arthur and Hubert;" and these at once established his reputation. The Royal Academy elected him a member in 1787, and he was welcomed into his seat by the president, his kind old master, Sir Joshua. Although, in a short time afterwards, the failure of Boydell threw him back upon portraiture, his fortunes did not cease to rise. Numerous sitters flocked to his studio; commissions for poetical and historical pieces occasionally dropped in; and in 1791 his earnings, which had been hoarded up with the utmost care, were fast swelling into a handsome competence. His fame, however, began to decline; his portraits could not stand comparison with the masterpieces of Lawrence, which were now beginning to come into the field; and all his open depreciation of his young rival could not prevent the public from thinking so. He tried moral painting in 1796, in the "Modest Girl" and the "Wanton," but found he could not compete with Hogarth. Falling back upon history, he produced "The Earl of Argyll in Prison," and "The Vulture and Snake." But the golden age of historical painting was passing away, and his own hand, weakened by age, was gradually forgetting its cunning. Last of all, he tried book-making, and in 1813 published a life of Sir Joshua Reynolds, which was chiefly valued on account of the sayings and anecdotes which it preserved. It was while the reputation of Northcote had thus failed to be sustained by himself, that it was revived by his newly-acquired friend, the celebrated William Hazlitt. The two acquaintances had frequent intercourse; the painter vented his pungent remarks and cutting gibes while his hand plied the brush mechanically, and the writer noted down the conversation as it proceeded. The result was, that the sayings of Northcote were published by Hazlitt in periodical sections in the *New Monthly Magazine*, under the title of *Boswell Redivivus*. The popularity which that series of papers secured confirmed the bond between the chronicler and his hero. A large work in 2 vols. 8vo, entitled *Titian and his Times*, was thus produced between the two in 1830. This was the last effort of Northcote. He died on the 13th July 1831. (Cunningham's *Lives of Painters*, &c.)

NORTHERN CIRCARS. See CIRCARS, *Northern*.

NORTH SEA, or GERMAN OCEAN, a part of the Atlantic Ocean, lying between Great Britain on the W. and Denmark and Norway on the E.; extends from N. Lat. 51. to 61., E. Long. 2. 30. to 7. 30. Its length is about 700 miles, its breadth about 420 miles, and its area about 270,000 square miles. Near the coasts of Norway, which are steep, and, though indented by deep fiords, send but few streams to the sea, the depth is the greatest, being about 190 fathoms; while the average depth of the whole sea is only 31. On the low southern shores the Elbe, Weser, Rhine, and Scheldt, which here discharge themselves, have

Northern
Circars
||
North Sea.

Northumberland. carried down immense quantities of sand, which have made the southern portions of the sea comparatively shallow; while on the coast of Great Britain the same effect, though to a less extent, has been produced by the Thames, the Ouse, the Humber, the Tyne, the Forth, and the Tay. The centre of the sea is occupied by several large sand-banks, the principal of which are, one extending from the Firth of Forth 110 miles to the N.E., another stretching nearly as far N.W. from the mouth of the Elbe, and the Dogger Bank, which lies between N. Lat. 54. 10. and 57. 24., E. Long. 1. to 6. 7. The North Sea has also some remarkable deep holes, such as the Little Silver Pit, off the Yorkshire coast, the Great Silver Pit, and the North North-East Hole. These abound in fish, especially cod, hake, ling, turbot, soles, mackerel, herring, &c.; and fishing is extensively carried on, both on the different shores of the sea, and on the Dogger Bank, where cod is obtained. The tides in this sea are formed by the great wave of the Atlantic which passes round the S. and N. of the British Islands. The tide-waves from the N. and S. meet on the coasts of Jutland, where the tides nearly neutralize each other. On entering the North Sea the height of the wave is about 12 feet; but the form of the shore, the nature of the bottom, and the direction in which it meets the land, cause it to vary somewhat in height at different places, and on the Humber it rises to 20 feet. The islands in this sea are of insignificant size, and are three in number—Heligoland, off the Elbe; the Isle of May and the Bell Rock, in the Firth of Forth. On all these, and on many other points, light-houses have been erected. The North Sea is connected with the English Channel by the Straits of Dover, and with the Baltic by the Skagerrack, the Cattegat, the Great Belt, the Little Belt, and the Sound.

NORTHUMBERLAND, an extensive county in England, situated on its northern extremity, upon the borders of Scotland, from which it is separated partly by the River Tweed, which, during the latter part of its course, flows between this county and Berwickshire, and partly by a line supposed to be drawn over the mountainous region on the W. and N.W., where it meets with Roxburghshire. The other boundaries are the German Ocean on the E., Durham on the S., and Cumberland on the W. On the N. are two small districts called Norhamshire and Islandshire, which, though belonging by their situation to Northumberland, formed a part of the county of Durham, along with another tract called Bedlingtonshire, on the S.E. By a recent act of Parliament these have been united to Northumberland, and the Tweed has thus become the northern boundary of the county. The town of Berwick, also on the N. of the Tweed, has been added to Northumberland for election purposes, but has still a separate jurisdiction, with a sheriff of its own. Lindisfarne, or Holy Island, on the N.E. coast, which in like manner belonged to Durham, is situated about two miles from the mainland, opposite to the mouth of the brook Lindis, and accessible to all kinds of conveyance at low-water. Although about nine miles in circuit, it contains little more than 1000 acres, the half of which is sand-banks. In this view, Northumberland is situated between 54. 48. and 55. 42. N. Lat., and between 1. 25. and 2. 41. W. Long. Its greatest extent from N. to S. is 64 miles, and from E. to W. it varies from about 46 miles, which is its usual breadth between the River Tyne on the S. and the Coquet on the N., till it terminates at the town of Berwick on the N., in a breadth of only 5 or 6 miles. The area is 1952 square miles, or 1,249,299 acres. Nearly one-third of the county is scarcely capable of beneficial cultivation.

It is divided into six wards, namely, Tyndale, Coquetdale, Glendale, Bamborough, Morpeth, and Castle; the first three comprising the western and mountainous district, and the second three the coast lands on the E. Besides these,

Northumberland. Northumberland includes the county of Newcastle. The maritime wards, though extending over only one-fourth of the county, are by far the most wealthy and populous, owing chiefly to the great coal-works in Castle ward, near the town of Newcastle, and along the banks of the Tyne. It contains five deaneries and seventy-three parishes, all of which are in the archdeaconry of Northumberland and diocese of Durham.

All the western side of this county is mountainous, from the boundary of Durham on the S. almost to the valley of the Tweed on the N.; but this extensive tract, comprising more than a third of the whole area, is not all of the same character. The northern, or Cheviot Hills, extending to about 90,000 acres, being for the most part green nearly to their summits, comprehending many narrow but fertile glens, and affording excellent pastures for the breed of sheep to which they have given their name; whilst those to the W. and S. are, in general, open solitary wastes, covered with heath, and of very little value. Along the coast, from the mouth of the Tyne to that of the Tweed, the country is, with few exceptions, level and rich, with a soil which, in some places, is a strong clay, and in others a dry loam, but almost everywhere very productive, under the enlightened system of cultivation which prevails so generally throughout Northumberland. The climate of Northumberland is colder, and the time of harvest later, than in the more southerly parts of England. The western and upland regions are cold and bleak; but near the sea, although chill east winds sometimes prevail, the temperature is considerably milder and warmer. The coast is generally low, and has numerous bays and headlands; while near to the mainland there are several small islands which are included in the county.

The principal rivers of the county are the Tyne, Blyth, Wansbeck, Coquet, Aln, and the Tweed, all of which fall into the sea, carrying with them the tribute of many smaller streams. The Till, which empties itself into the Tweed, is also a considerable rivulet. The Tyne and the Tweed are by far the most important, the tide flowing up the former 16 miles, and up the latter 8 or 10 miles; whilst the navigation of the other rivers is confined to a small distance from their mouths. Both of these have long been celebrated for their salmon fisheries, which are, however, much less productive than formerly. Those on the Tyne barely supply the local consumption, but the Tweed fisheries afford a valuable article of trade with London, to which the fish are sent packed in pounded ice, by which means they are presented in the market in nearly as fresh a state as if they had been newly taken from the water.

Northumberland has long been distinguished for its subterranean treasures, which are the main source of its wealth and cause of its populousness. Of these, coal, which abounds in most parts of it, is by far the most important. It is of the best quality in the south-eastern quarter, on the banks of the Tyne, whence those vast quantities are exported which supply the great consumption of the metropolis, as well as other British and foreign ports. The coal is all of the kind called "caking coal," which melts and runs together in the fire, and, when of the best quality, leaves very little ashes. Calculations have been made as to the extent of this tract, the quantity of coal which it may contain, and the period when it must be exhausted; but upon this latter point there is a great difference of opinion, some estimating that the supplies must cease in three hundred years, some not in less than eight hundred, whilst by others it is held to be almost inexhaustible. Of the coal found in Bamborough, Islandshire, and Glendale ward, the seams are in general thin, and the quality inferior, not caking nor burning to a cinder, but yielding a great quantity of ashes. This is used only for home consumption and for burning limestone, a purpose for which it is well adapted. Through

North-
berland.

all this district coal and lime are generally found together: but the south-eastern quarter, which is so rich in coal, is destitute of limestone. Lead ore abounds in the mountains on the S.W., particularly towards the head of that branch of South Tyne called Allendale, where it has long been wrought to a considerable extent. Iron ore is found in many parts; stone marl near Tweedside, shell marl in Glendale ward, and various sorts of sandstone or freestone are obtained in almost every quarter, some of it affording tolerable flags for roofing and for floors. In the sandstone quarries excellent grindstones are obtained, and a great many are exported.

The agriculture of Northumberland is an object which is only second in interest and importance to its coal-works. Almost all those branches of rural economy for one or more of which other districts are celebrated, may here be found combined into one system, and conducted upon the same farms. One finds here, in great perfection, the Leicester and Southdown sheep and the short-horned cattle of Durham and Yorkshire; the turnips of Norfolk, cultivated upon the drill system of Scotland; the well-dressed fallows of East Lothian and Berwickshire; and that regular alternation of tillage and grazing which is, of all other courses of cropping, the one best adapted to sustain, and even to improve, the productiveness of the soil. These remarks apply in an especial manner to the northern part of the county, where the farms are in general large, and the occupiers men of education and liberal acquirements. This quarter has been long distinguished as a school of agriculture, to which pupils are sent, some of them gentlemen of fortune, from various parts. The common period of leases, at least in the northern district, is twenty-one years, although many are shorter, and upon a few estates no leases are granted. By the account taken for the purpose of levying the property-tax in the year 1843, it was found that the annual value of the real property amounted to L.1,542,434. It may be worthy of remark here, that at the seat of the Earl of Tankerville, called Chillingham Castle, there still exist in the forest some remains of the herds of wild cattle which are supposed to have formerly abounded in this island, and to have been the origin of our race of cows.

This county is traversed by two principal lines of railway, extending from Newcastle, the one northwards along the coast to Berwick, and the other westwards to Carlisle. The length of the former, which is entirely in Northumberland, is 66 miles, while the latter extends 41 miles before it leaves the county. There are also shorter lines connecting Newcastle with North Shields, Tynemouth, and Blyth.

Northumberland is not eminently a manufacturing county. Some wool-combing is carried on at Hexham, and some thread is spun in the villages; but the chief branches of manufacturing industry are those that depend upon the collieries, and are chiefly carried on within and around the town of Newcastle, to which head in this work the reader is referred.

Of all the English counties none is so rich as this in remains of the Roman era. Among these, the most important is the famous wall built by Agricola against the Picts, and subsequently repaired and improved by Hadrian and Severus. It extends across the S. of the county from the Tyne to the Solway Firth. There is a great Roman road running northwards through Northumberland into Scotland; and there are, besides, many Roman camps and stations.

The population of the county at the six decennial enumerations has been as follows:—In 1801 it amounted to

168,078, in 1811 to 183,269, in 1821 to 212,589, in 1831 to 236,959, in 1841 to 266,020, and in 1851 to 303,568. The number of inhabited houses in 1851 was 47,737. Northumberland contained, in 1851, 488 churches, with 136,066 sittings. Of these, 154 belonged to the Church of England, 198 to Methodist sects, 68 to Presbyterians, 20 to Roman Catholics, and 14 to Independents. There were also 359 Sunday schools—131 Episcopalian, 115 Methodist, 55 Presbyterian, and 18 Independent. The number of scholars was 29,687. Of ordinary schools there were 642, with 37,289 scholars.

The title of Duke of this county belongs to the family of Percy, which passed into the female line in the last century. The Earl of Carlisle derives his second title from the town of Morpeth. This county is included in the northern circuit. The assizes are held at Newcastle thrice a year, and the quarter-sessions successively at Newcastle, Morpeth, Hexham, and Alnwick. For the purposes of election two divisions are formed, each returning two members. The elections for the northern division are held at Alnwick, and the polling-places are, besides that town, Berwick, Elsdon, Morpeth, and Wooler; for the southern they are held at Hexham, and the other polling-places are Bellingham, Haltwhistle, Newcastle, and Stamfordham. Besides Newcastle and Berwick, each of which returns two members, Morpeth, which, previous to the Reform Bill, had two members, still retains one. By the same act one member was given to the borough of Tynemouth, which includes the town of North Shields, with a considerable rural district around it. The towns containing more than 2000 inhabitants, with their population in 1851, were the following:—

Newcastle.....	87,784	Alnwick.....	6231
Tynemouth.....	29,170	Hexham.....	4601
Berwick.....	15,094	Blyth.....	2060
Morpeth.....	10,012		

The noblemen's and gentlemen's seats are generally handsome edifices, but those especially worthy of mention are Alnwick Castle, the residence of the Duke of Northumberland, and Chillingham Castle, that of the Earl of Tankerville. Alnwick Castle is at present undergoing most extensive improvements at an enormous cost, which, when completed (in about 1860), will render it the most complete and magnificent baronial residence in England. Lord Ravensworth resides at Eslington Park during a portion of the year, but his principal seat is Ravensworth Castle, in the county of Durham. Howick Hall is a handsome building by Paine, under whose superintendence many of the mansions of the Northumbrian gentry were rebuilt about the middle of the last century. Bamburgh Castle, an ancient royal fortress, and the seat of the Northumbrian kings during the Heptarchy, came into the possession of Nathaniel, Lord Crewe, Bishop of Durham, who left extensive estates to trustees for charitable purposes. The castle has been restored and fitted up for the occasional residence of the trustees. Ford Castle was rebuilt about a century ago by the late Lord Delaval. It is now the property of the Marquis of Waterford, whose agent occupies the castle. The modern additions are in bad taste, but there are interesting remains of the ancient fabric, long the residence of the noted border family of Heron. The remains of castles now in ruins are Norham, Etal, Dunstanburgh, Warkworth, Prudhoe, Langley, and Thirlwall, with many others of minor importance. Of Wark and Mitford little remains but the foundations. Bothal has been fitted up as a residence for the agent of the Duke of Portland; and Morpeth for the agent of Lord Carlisle. (J. H.)

NORTH-WESTERN PROVINCES.

Divisions
and
Districts.

THE NORTH-WESTERN PROVINCES OF BENGAL form one of the great political divisions of Hindustan, comprehending a vast tract of territory, and constituting a sort of vice-presidency under the chief government of India. The administration is conducted by an officer, bearing the title of lieutenant-governor, who is appointed by the governor-general in council. These provinces, intersected by the Jumna and the Ganges, lie between Lat. 23. 51 and 30. 26., Long. 75. 20. and 84. 40.; and are bounded on the N. by the Deyra Dhoon, Kumaon and Nepal; on the E. by Nepal, Oude, and the lower provinces of Bengal; on the S. by the lower provinces of Bengal and the native state of Rewah; and on the S.W. by Bundelcund, Scindia's territory, and Rajpootana. The whole territory, comprehending an area of 76,190 square miles, with a population, according to the census of 1852-53, of 30,473,927, is distributed into six divisions and thirty-three districts. In the following list the names in capitals are those of the provinces, the others of districts. But there are districts also bearing the same name as the provinces, except in Rohilcund. The order is from north to south.

| 6. Goorgaon. | 5. Etawah. | 6. Ghazeepore. |

Under the general arrangement for the government of India (3d and 4th William IV., cap. 85), the then existing Presidency of Bengal was to be divided into two Presidencies,—one retaining the previous name, the other to be called the Presidency of Agra. This plan, however, was not carried out; and by an act subsequently passed (5th and 6th William IV., cap. 52), power was given to the East India Company to suspend its operation, and to the governor-general in council to appoint, during such suspension, a lieutenant-governor of the north-west provinces, exercising his powers within an extent of territory to be defined by the authority from whom he received his appointment, and with such limitations as the same authority might deem fit. Agra is the seat of the government thus established, from which circumstance the officer administering it is usually styled the Lieutenant-Governor of Agra. In addition to the limits above defined, the jurisdiction of this functionary extends over some considerable tracts denominated the non-regulation districts, comprising the Saugor and Nerbudda territories, the Butty territory, the districts of Gurwhal, Ajmere, &c. By the Act of the Go-

vernor-General in council, dated the 9th of January 1858, Mutiny of Delhi and Meerut, or some portions thereof, were placed under the Chief Commissioner of the Punjab. 1857.

As the great mutiny of the Bengal army in 1857, though extending in some instances to Lower Bengal, and other parts of India, was chiefly confined to the north-west provinces, the insertion of the present article seems to afford a fitting opportunity for giving a summary of the principal occurrences connected with that extraordinary event. At the commencement of the year just mentioned a degree of uneasiness was first observed in a brigade of native infantry stationed at Barrackpore, and the natives attached to the depot of musketry at Dum Dum, in the vicinity of Calcutta. A rumour had been insidiously spread that the sepoys were to be forced to embrace the Christian faith, and that as a prelude to the change, and with the view of entrapping the troops into a loss of caste, the government had given orders that the grease employed in the arsenal, in the manufacture of cartridges for the new Enfield rifle, should be composed of the fat of pigs and cows. In using this description of cartridge one end is bitten off previous to loading; and as the Mohammedan regards the hog as impure, while the Hindoo looks upon the cow as a sacred animal, it would be alike repugnant to the religious prejudices of both creeds to apply the new ammunition to the mouth. The rumour appears to have been first put in circulation at Dum Dum. At this place a low-caste Hindu meeting a Brahmin sepoy, attached to the depot of musketry, solicited a draught of water from his lotah or drinking-cup. The Brahmin refused, observing, "I have scoured my lotah, and you will defile it by your touch." "Caste!" was the taunting rejoinder, "you think much of your caste, but wait a little; you are all going to eat bullock's fat, and then what will become of your caste?" The news spread rapidly through the cantonment, and soon extended to Barrackpore. At both stations it produced a high degree of excitement. An investigation into the matter was forthwith instituted under the orders of the government. In the course of the inquiry it was ascertained that hog's lard did not in any way enter into the composition of the grease. At the same time, it could not be satisfactorily shown from what description of animal the tallow was obtained; and, as under this doubt it would have been impossible to convince the sepoys that the ingredients were of an inoffensive character, the government at once determined to remove all cause of objection by ordering the cartridges to be issued altogether free from grease. A notification was accordingly promulgated abolishing the use of fat in the composition; but as the application of some greasy substance was absolutely necessary for the purpose of lubricating the bore of the rifle, the men were directed to apply with their own hands whatever mixture they might prefer. The alleged grievance being thus promptly redressed, and a full¹ explanation of the matter having been made by the commanding officers, both at Dum Dum and

¹ The address to the troops by Major-General Hearsey, commanding at Barrackpore, is remarkable for its manly and straightforward character. In a letter to the government, dated the 11th February 1857, he observes,—“I must mention that I had the whole brigade paraded on Monday afternoon, the 9th, and myself energetically and explicitly explained, in a loud voice, to the whole of the men the folly of the idea that possessed them, that the government or that their officers wished to interfere with their caste or religious prejudices, and impressed on them the absurdity of their for one moment believing that they were to be forced to become Christians. I told them the English were Christians of the Book, *i.e.*, Protestants; that we admitted no proselytes but those who, being adults, could read and fully understand the precepts laid down therein; that if they came and threw themselves down at our feet, imploring to be made “Book” Christians, it could not be done; they could not be baptized until they had been examined in the tracts of the Book, and proved themselves fully conversant in them, and then they must of their own goodwill and accord desire to become Christians of the Book ere they could be made so. I asked them if they perfectly understood what I said, especially the 2d Grenadiers; they nodded assent: I then dismissed the brigade. I have since heard from officers commanding regiments, that their native officers and men appeared quite (“koosh”) pleased, and seemed to be relieved from a heaviness of mind that had possessed them.”

Mutiny of
1857.

at Barrackpore, the sepoy appeared perfectly satisfied that no intention existed of interfering with their religious prejudices. Shortly afterwards, however, a similar spirit of discontent developed itself at Berhampore, a military cantonment near Moorshedabad. An escort party of the 34th native infantry from Barrackpore had made known to the sepoy of the 19th regiment native infantry stationed at Berhampore the objections which had been urged against the new cartridges by their comrades at Barrackpore and Dum Dum; and though they had been apprised of the remedial measures which had been adopted, a conviction seemed nevertheless to be gaining ground that the government were steadily bent upon making the sepoy lose caste by forcing them to handle impure things. The men were consequently ripe for outbreak. On the 26th of February the regiment was ordered to parade for exercise with blank ammunition. When the cartridges¹ were about to be issued, the men, one and all, refused to receive them, upon the ground that the paper of which they were made was glossy, and when burned gave out a smell of animal fat. The plea was wholly without foundation. Upon being analyzed the paper proved to be free from all greasy or oily matter. Under these circumstances, it became obvious that any farther continuance in a conciliatory course would be most impolitic. From the moment that the main facts of the outbreak were established, every member of the government felt satisfied that no penalty short of the disbandment of the regiment would meet the case. A severe example, it was hoped, would have the effect of convincing the native troops that they would only bring ruin upon themselves by failing in their duty to the state, and in obedience to their officers. In this expectation the men were marched down to Barrackpore, where, on the 31st of March, the regiment was formally disbanded. The example was at first believed to have produced the desired effect; and it was asserted that a better spirit had begun to prevail among the native troops. But almost immediately after, a European detachment was hurried down from Dum Dum to Calcutta, where an alarm had broken out, upon its becoming known that two sepoy of the 2d regiment of native infantry, while on duty at the fort, had been detected in an attempt to bring over the guard of the Calcutta Mint. In the following month a sepoy, and one of the native officers of the 34th native infantry stationed at Barrackpore, were found guilty of mutiny, and sentenced to be hung; and on the 6th of May the general insubordination of the sepoy rendered it incumbent upon the government to disband and dismiss from the service seven companies of the same regiment quartered at that place. At this juncture, moreover, information reached Calcutta of the mutinous conduct of the 7th regiment of the Oude irregular infantry at Lucknow.

General
outbreak.

These partial mutinies at Barrackpore, Fort William, Berhampore, and Lucknow, indicating a wide-spread spirit

of disaffection, were but the forerunners of the general revolt of almost the entire native army of Bengal. About the middle of May, the startling intelligence reached Calcutta that the flame of insurrection had burst forth at Meerut and Delhi; that six regiments quartered in those cities, viz., the 11th and 20th native infantry, and the 3d light cavalry, at Meerut, and the 38th, 54th, and 74th native infantry at Delhi, had risen in open mutiny, and that the insurgents had seized and retained possession of the city of Delhi. The announcement excited an all-absorbing interest throughout all classes of the community. Every one felt that a crisis was at hand, demanding from those who were called upon to encounter it the exercise of a vigorous judgment, combined with the most resolute courage and the greatest promptitude of decision. The government were not slow in proving themselves equal to the occasion. A proclamation forthwith appeared, disavowing all intention on the part of the state to interfere with the caste or religion of its subjects;² and this preliminary step being taken, Lord Canning proceeded to meet the emergency with all the energy and determination which we are wont to admire in the earlier history of our Indian conquests. The one great object was to procure European troops. For this purpose prompt measures were adopted for intercepting the military force then on its passage from England to China; earnest requisitions for reinforcements were simultaneously dispatched to the Mauritius, Ceylon, the Cape of Good Hope, and Great Britain; and these were followed by the most vigorous preparations for concentrating in the disturbed districts the scattered military resources of the empire. In the following narrative, an attempt is made to connect the leading events which mark the progress of this momentous outbreak.

Mutiny of
1857.

Early in May 1857, the 3d regiment of Bengal light cavalry, stationed at Meerut, refused to continue the use of the old cartridges; none of the new ammunition, as already observed, having been issued to any native regiment. For this act of mutiny all the men of the regiment armed with carbines were tried by court-martial, and eighty-five of their number sentenced to imprisonment for ten years with hard labour. The sentence was read at a general parade of the troops on the 9th of May, and the prisoners, after being ironed on parade, were marched off to the jail. Two other native regiments, the 11th and the 20th infantry, were also quartered at Meerut; and on the following day, the 10th of May, the men of these corps broke out in open mutiny, and joined the disaffected light cavalry. Col. Finnis, of the 11th regiment, attempting to expostulate with the men, was shot by the insurgents of the 20th regiment. Several other British officers were then singled out as victims, and all Europeans—men, women, or children—upon whom the miscreants could lay hands, were ruthlessly murdered. The loss of life extended to about forty individuals. In the course of the night the mutineers,

¹ These were the old cartridges which the regiment were in the habit of using. It is, indeed, worthy of remark, that the new cartridges had been issued only to the musketry depots at Dum Dum, Umballah, &c., and not to any native regiment. They were adapted exclusively to the new Enfield rifle; and as the native regiments were armed hitherto with the common musket, it would have been useless to have issued them.

² The proclamation ran as follows:—"The Governor-General of India in council has warned the army of Bengal, that the tales by which the men of certain regiments have been led to suspect that offence to their religion, or injury to their caste, is meditated by the Government of India, are malicious falsehoods. The Governor-General in council has learnt that this suspicion continues to be propagated by designing and evil-minded men, not only in the army, but amongst other classes of the people. He knows that endeavours are made to persuade Hindus and Mussulmans, soldiers and civil subjects, that their religion is threatened secretly, as well as openly, by the acts of the Government, and that the Government is seeking in various ways to entrap them into a loss of caste for purposes of its own. Some have been already deceived and led astray by these tales. Once more, then, the Governor-General in council warns all classes against the deceptions that are practised on them. The Government of India has invariably treated the religious feelings of all its subjects with careful respect. The Governor-General in council has declared that it will never cease to do so. He now repeats that declaration, and he emphatically proclaims that the Government of India entertains no desire to interfere with their religion or caste, and that nothing has been or will be done by the government to affect the free exercise of the observances of religion or caste by every class of the people. The Government of India has never deceived its subjects. Therefore the Governor-General in council now calls upon them to refuse their belief to seditious lies. This notice is addressed to those who hitherto, by habitual loyalty and orderly conduct, have shown their attachment to the government, and a well-founded faith in its protection and justice. The Governor-General in council enjoins all such persons to pause before they listen to false guides and traitors, who would lead them into danger and disgrace."

Mutiny of
1857.

Delhi.

having previously rescued the eighty-five prisoners of the light cavalry who had been sentenced to hard labour, and having fired the cantonments, retired in the direction of Delhi. This place the mutineers reached on the 11th. Crossing the Jumna by the bridge of boats, they made direct for the palace of the king, where, being promptly admitted, they sallied forth into the town. Here they were met by the Delhi troops, consisting of the 38th, the 54th, and the 74th native infantry. Both parties evidently understood each other. The three regiments at once fraternized with the rebels. This being done, they turned upon their officers, many of whom they shot or cut down; then continuing the career of atrocity commenced at Meerut, they proceeded to murder all Europeans wherever they could be found. The number who thus perished is said to have been very great. The next step of the mutineers was to take possession of the fort and city, and to secure the bridge of boats over the river. Lieutenant Willoughby, the commissary of ordnance, held charge of the magazine, and finding that the rebels were escalading the walls by means of ladders, which had been supplied from the palace, gallantly blew up the building. Unhappily, this heroic soldier received severe injuries, and did not long survive the daring act. All the Europeans within the palace were slaughtered with the concurrence, if not by order of the king, and the restoration of the house of Timour was proclaimed. Delhi, thus captured, remained in the occupation of the mutineers; and no inconsiderable portion of the Bengal army was now arrayed in armed resistance against the lawful rulers of the country. On the part of the British, it was felt that the prompt recapture of the city was of the first importance, it being obvious that the preservation of order throughout the north-west provinces was mainly dependent upon the early and signal discomfiture of the rebels. Delay, however, was unavoidable. The commander-in-chief, General Anson, hastening down to Delhi from the hill station of Simlah, reached Kurnaul on the 25th of May, where he was attacked by cholera, and fell a victim to the disease on the 27th of May. Upon this the command of the army devolved upon Major-General Sir H. Barnard, who, having been joined by the troops of the Rajahs of Jheend and Pateela, moved on towards Delhi, and reached Allipore, 10 miles from the city, on the 5th of June. Before, however, the new commander could reach the captured city, the insurgents sallied forth in great force, and attacked a portion of the troops from Meerut under Brigadier-General Wilson, at Ghazee-ood-deen Nuggur. The attack was made on the 30th of May, and repeated on the 31st; but the assailants were thoroughly beaten and dispersed, leaving behind them five guns, and large stores of ammunition. Our loss on the two occasions amounted to 23 killed and 31 wounded. On the 8th of June, General Barnard advanced from Allipore, and being joined by Brigadier Wilson, made a spirited attack upon the enemy's intrenched outposts at Badlee-ke-serai, captured the heights in front of Delhi, together with 26 guns, and drove the rebels, dispirited, within the walls of the city. The position thus secured by the British extended from the river on the left, along the ridge facing the north side of the city as far as the Subzee Mundee suburb on the right, where the hilly ridge terminates; the distance from the city walls averaging from 1200 to 1500 yards. On this occasion a most determined resistance was shown by the enemy, and the loss of the British was no less than 51 killed and 134 wounded or missing, with 63 horses. Next day, and again on the 10th and the 11th, the enemy attacked the British position, but were repulsed, and retreated within the city. On the 12th a very serious attack was made by the mutineers on the flagstaff picquet, nearly in the centre of the British position, and a few hours afterwards, at the Subzee Mundee, on the British extreme right. The 60th native infantry, which had been detached to

Rohtuck, and had there mutinied and joined the insurgents at Delhi, suffered much in this encounter. An assault upon the city had been arranged for the 13th of June, but, owing to the mistake of a superior officer in delaying to withdraw the picquets—without which the columns of attack would have been too weak—was abandoned. On the 15th the rebels again made a sortie, attacked the Metcalfe picquet, and tried to turn the left flank of the British, but after a sharp action, were repulsed with great loss. On the 17th the enemy opened a very heavy cannonade to cover some batteries they were constructing. A single shot fired by them killed Ensign Wheatley of the 54th native infantry, and killed or wounded nine men. At 4 P.M. Majors Tombs and Reid led two columns to the attack of the works the rebels had just commenced, and destroyed them, losing only 18 killed and wounded. On this day the mutineers were reinforced by the Nusseerabad brigade, consisting of the 2d company 7th battalion artillery, No. 6 horse battery, the 15th and 30th native infantry, and a few troopers of the 1st Bombay lancers. On the 19th the enemy attacked the British position in great force, a very large body of them having got in the rear of it. The action lasted till late at night, and was renewed next morning. It ended in the retreat of the rebels, but the British loss was 10 officers, 89 men, and 60 horses killed, wounded, or missing. Lieutenant-Colonel Yule, of the 9th lancers, was among the killed. On the 21st the rebels were joined by the 6th light cavalry, the 3d, 36th, and 61st native infantry from Jullundur and Phillour. On the 23d of June, being the centenary of Plassey, the rebels made a determined sortie, which was not repulsed without severe loss to the British. A gun was disabled, and 4 officers and 156 men were killed or wounded. On the 27th, and again on the 30th, sorties were made, which the British repulsed, with the loss to themselves of 62 killed and wounded on the first occasion, and 46 on the second; but they were now joined by fresh troops, which, on the 3d of July, made up the besieging army to 6600 men of all arms. It was now again proposed to attempt to take the city by a *coup de main*; but the idea was again abandoned. On the 1st and 2d of July, the 8th irregular cavalry, the 18th, 28th, 29th, and 68th native infantry, No. 15 horse battery, and two 6-pounders, from Rohilcund, marched into the city across the bridge of boats. On the 3d the rebels moved a force of several thousand men against Allipore, which they plundered; but next day the plunder was retaken by Major Coke after a sharp skirmish. Further attacks were made by the rebels on the 4th and 9th of July, in the last of which the British loss amounted to 211 killed and wounded.

General Barnard was attacked with cholera, and died on the morning of the 5th. The vacancy was supplied by General Reed; but before the close of the month this officer also was compelled, by severe illness, to hand over the chief command to General Wilson. On the 9th the enemy made a spirited sortie, and 100 of their horse charged right into camp, cutting down Lieutenant Hills and some camp followers. At the Subzee Mundee the fire was very hot. The total British loss was 9 officers and 214 men killed and wounded. In spite of past defeats the mutineers, on the 14th of July, made a bold attempt to capture the British batteries. The attempt proved abortive; but so fierce was the onset that the assailants inflicted a loss upon their opponents of 16 officers, including Brigadier Chamberlain, and 194 men killed and wounded. On the 18th the last serious engagement in the Subzee Mundee took place, when the total of British casualties was 11 officers and 80 men. The British works were henceforward so complete in this place that the enemy could effect nothing. Again, on the 23d, the rebels came out in considerable strength, and moved upon the British position at the Metcalfe battery. Here they were taken in flank by a force under Brigadier

Mutiny of
1857.

Mutiny of
1857.

Showers, and put to precipitate flight. A lull of a few days succeeded; but on the 31st of July, the anniversary of the Mohammedan festival, styled "Buckree Eed," the enemy poured out in great force, and commenced a general attack upon the advanced posts of the British. The contest was continued without intermission, day and night, until the morning of the 2d of August. Never before had the rebels displayed so great an amount of determination. Although their courage invariably failed them when about to make the final rush, yet never before had they so closely approached the British breastworks. Throughout this prolonged encounter, the British, well under cover, inflicted terrible punishment upon the enemy, with slight loss to themselves; and when, about noon on the 2d, the rebels drew off the dead and wounded, who lay in heaps before the British works, of the British only 46 of all ranks were wounded. A few days later (12th of August), a battery which had been opened by the enemy outside the walls, bearing upon the point known as Metcalfe House, was captured by a force under Brigadier Showers, who was severely wounded. In this gallant affair the casualties among the British extended to 117 killed and wounded; many of the latter, however, were but slightly injured. It may be here stated that, inclusive of three or four minor contests which it has not been thought necessary to notice, the number of engagements fought in front of Delhi from the date of the insurrection to the commencement of August, amounted to no less than twenty-three. In these the aggregate loss of the British was 318 killed and 1062 wounded. Of the former, 22 were officers and 296 privates; and of the latter, 72 were officers, the remainder consisting of rank and file. With respect to the mutineers, though their losses from their multiplied defeats must have been enormous, still their numerical strength was throughout far superior to the English; for, in addition to the reinforcements already mentioned, they had received a wing of the 12th native infantry, the 14th irregular cavalry, and half No. 18 light field battery from Jhansi, and the Neemuch brigade—viz., a troop of horse artillery, a wing of the 1st light cavalry, the 72d native infantry, the 7th Gwalior contingent, and the cavalry and infantry of the Kotah contingent, which arrived late in July, besides many smaller bodies.

After the fruitless attempt of the 1st of August, the enemy appear to have lost all hope of dislodging the British, and for upwards of three weeks remained comparatively inactive, under shelter of their fortifications. On the 8th of August Brigadier Nicholson arrived in the camp with a strong brigade from the Punjab, bringing up the strength of the English army to 8122 rank and file, besides 1535 sick, and 304 wounded. On the 13th a body of the enemy's cavalry left Delhi by the Nujufgurh road, with a view, it was thought, of interrupting the British communications with the Punjab. Several parties of them were cut up by Lieutenant Hodgson with his horse and the guide cavalry, and he returned to camp on the 22d. On the 24th a strong column of the rebels with 18 guns, proceeded in the Bahadurgurh direction, to intercept the field-train coming to the British camp from Ferozepore. General Wilson, penetrating the design, despatched a force in pursuit, under Brigadier Nicholson, who came up with the rebels on the 26th, posted at Nujufgurh. Here he attacked them with great success, captured all their guns, and drove them back broken and dispirited to Delhi. Their loss was estimated at between 300 and 400; that of the British was 95 killed and wounded. On the morning of the 27th a sortie was made from Delhi, under the impression that the British force was much weakened by the despatch of the force under Briga-

dier Nicholson, who had not yet returned; but the attack was easily repulsed.

By the 6th of September, all the British reinforcements that could be looked for, together with the siege-train, had arrived. It was now determined to commence regular siege operations, and the effective force for that purpose amounted to 8748 men. There were besides in hospital 2977. The Europeans were—of artillery, 580; cavalry, 443; infantry, 2294. There were also the Cashmere contingent of 2200 men with 4 guns, and some hundred men under the Jheend Rajah.¹

The north face, from which side the stronghold of the rebels was to be attacked, comprised the Moree, Cashmere, and Water bastions, with the curtain-walls connecting them. Four batteries armed with heavy guns having been established in commanding positions, and within a short distance of the walls, the bombardment commenced on the 11th of September. In planning the attack one great object kept in view was to divert attention from the real point of the intended assault, and in this the British commander completely succeeded, the enemy obviously concluding, from their preparations that the attack was to be made from a point more to the right. On the night of the 13th two breaches near the Cashmere and Water bastions being examined by the engineers, and pronounced practicable, orders for the assault were issued to take place at day-break the following morning. The arrangements for the storming, which was to be made by four columns and a reserve, were as follows:—1st column, Brigadier-General Nicholson,—Her Majesty's 75th regiment, 1st Bengal fusiliers, and 2d Punjab infantry: to storm the breach near the Cashmere bastion, and escalate the face of the bastion. 2d column, Brigadier Jones, C.B.,—Her Majesty's 8th regiment, the 2d European Bengal fusiliers, and 4th Sikh infantry: to storm the breach in the Water Bastion. 3d column, Colonel Campbell,—Her Majesty's 52d regiment, the Kumaon battalion, and 1st Punjab infantry: to assault by the Cashmere gate after it should be blown open. 4th column, Major Reid,—Detachment of European regiments, Sirmoor battalion, Guide infantry, and detachment of Dograhs: to attack the suburb Kisesungunge, and enter the Lahore gate. 5th column, Brigadier Longfield,—Her Majesty's 60th Rifles, Kumaon battalion, and 4th Punjab infantry: the reserve.

At four o'clock A.M. the several columns were marched to their respective positions, the heads of Nos. 1, 2, and 3 being concealed until the moment for action should arrive. The signal for the assault was to be the advance of the Rifles to the front to cover the heads of the columns by skirmishing. Upon the word of command being given, the Rifles dashed to the front with a shout, skirmishing along and through the low jungle which extended to within 50 yards of the ditch. At the same moment Nos. 1 and 2 columns, the one headed by General Nicholson and the other by Brigadier Jones, and consisting respectively of 950 and 850 men, emerged from the Koodsee Bagh, their place of concealment, and steadily advanced towards the breaches. On attaining the open space they were met from the front and both flanks by a storm of bullets, and officers and men fell fast on the crest of the glacis. For ten minutes it was found impossible to get the ladders down into the ditch, but the resolution of the British soldier carried all before it. The scarp was ascended, and with a cheer and a rush both breaches were won, and the enemy fled in confusion. In the meantime the third column, consisting of 950 men under Colonel Campbell of Her Majesty's 52d light infantry, made direct for the Cashmere gate, preceded by the explosion party under Lieutenants Home and Salkeld of the en-

Mutiny of
1857.

¹ The British troops actually engaged in the recapture of the city amounted to 2100 men.

Mutiny of
1857.

gineers. This little band, advancing in broad daylight to the gateway in the teeth of a sharp fire of musketry, coolly proceeded to adjust the powder bags. During the daring enterprise Lieutenant Salkeld received two gunshot wounds. His first shot was through the arm; notwithstanding this he went on to the gate, and while assisting in fastening the bags on the spikes, he was shot through the thigh, and fell. Sergeant Carmichael stepping forward to fire the train, was shot dead. Sergeant Burgess then made the attempt with better success, but paid for it with his life. Sergeant Smith, believing that Burgess had also failed, sprang forward, but seeing the train alight, threw himself into the ditch, and escaped the effects of the explosion. A tremendous crash announced that the gate was blown in, and the 3d column rushed to the assault, and entered the town at ten o'clock, just as the 1st and 2d columns had won the breaches. To four of the little band of heroes who accomplished the destruction of the gate the Victoria cross was afterwards awarded, viz., to Lieutenants Home and Salkeld, of whom the former was killed on the 1st of October by the premature explosion of a mine in destroying the fort of Malagurh, and the latter died of his wounds received at Delhi. The other two on whom the cross was bestowed were Sergeant Smith and a soldier of Her Majesty's 52d, who bound up Lieutenant Salkeld's wounds. General Nicholson having formed the troops within the walls, directed his advance along the ramparts, occupying the defences as far as the Moree bastion. Here, while endeavouring to penetrate still further in the direction of the Lahore gate, this most able, zealous, and gallant soldier, whose exploits during the Afghan and Sikh wars, and recent victory at Nujufgurh, had covered him with glory, received a wound at the head of the advancing column, which, on the 23d of September, terminated in his death. Unhappily the 4th column, which had been destined to carry the suburb of Kishengunge and enter the Lahore gate, failed in the enterprise. The principal loss sustained by the assailants was due to the obstinate resistance they met with in clearing the way from the Moree bastion to the Caubul gate, in a vain attempt to take the Burn bastion, and in the repulse at Kishengunge. On the day of the assault alone the loss amounted to 1104 men killed and wounded, and 66 officers, exclusive of the losses of the Cashmere contingent, or Dograhs, who were completely routed by the rebels, and fell back to camp, leaving four guns in the hands of the enemy. The loss of the enemy is given at 1500 men. A permanent lodgement having been now effected, preparations were made on the 15th for shelling the rebels out of the palace, the fort of Selimgurh, and the other strong positions of the city. At dawn on the 16th the magazine was stormed. In it were captured 125 pieces of cannon. The palace now lying well exposed from this point, the guns opened upon it from the inclosure. The Kishengunge battery, which had repulsed the 4th column, was now evacuated by the enemy, and the guns there taken swelled the number of captured pieces to 200. On the 16th a chain of posts had been established from the Lahore gate to the magazine, and on the 19th the line was advanced to the Chandnee Chouk, the principal street of the city. By the last mentioned day the resistance of the mutineers had become less decided; and in the evening of that day the Burn bastion was captured by surprise, and early next morning the Lahore gate and Garstin bastion were taken and held. At length the enemy maintained only a desultory warfare from the tops of the houses; and on the 20th of September, after an arduous struggle, continued during seven days, the labour of the gallant troops were crowned with complete success, and the city of Delhi was once more in the exclusive possession of the British. Large bodies of the mutineers effected a timely escape. Among the fugitives were the king of Delhi and his two sons and grandson. The royal party fled in disguise

VOL. XVI.

Mutiny of
1857.

along the road south of the city, the king being accompanied by his favourite wife the Begum Zeenut Mahal, "the Ornament of the Palace." On the 21st of September the king surrendered to Captain Hodson, who succeeded also in capturing his two sons, Mirza Mogul and Mirza Khizr Sultan, together with his grandson, Mirza Abu Bukr, at the tomb of Humayoon, about 5 miles from Delhi. The life of the king, now nearly ninety years of age, has been spared, and he may be safely allowed to pass the remainder of his days in peaceful exile. Not so the younger princes of the family. His sons and grandson, who were known to have taken an active part in the rebellion, on being taxed with their guilt, craved for mercy. But stern justice alone was to be dealt to them, and they were at once sentenced to be shot. Their execution took place at the Delhi gate on the 22d September. After the recapture of the city, General Wilson, then suffering from severe illness, resigned the command of the field force to General Penny, who, on the morning of the 24th of September, despatched Lieutenant Colonel Greathed of Her Majesty's 8th regiment, with a strong moveable column to clear the Doab, and endeavour to open communications with General Havelock at Cawnpore.

Cawnpore, one of the great military stations of the East India Company, is situated on the right or western bank of the Ganges, immediately opposite to the territory of Oude. In the spring of 1857, the military quartered here consisted of three regiments of native infantry and one of native cavalry, together with a detachment of Her Majesty's 84th regiment. For some weeks previous to the outbreak, the native troops were known to have largely participated in the general excitement caused by the insidious rumours regarding the de-filed cartridges. Symptoms of insubordination had been manifested from time to time in the ranks; and at length, on the night of the 4th of June, the 1st regiment of infantry and the 2d light cavalry rose in open mutiny. At their head appeared a Hindoo rajah known as Nana Sahib. This monster in human form was the adopted son of the late ex-Peishwa, Bajee Rao of Poona, and as such he had laid claim to the reversion of the pension which the latter enjoyed from the British. His pretensions, however, were overruled by the government, and his subsequent atrocities would thence appear to have been prompted by personal resentment. Nana had been on terms of intimacy with most of the British officers at Cawnpore. He spoke English, possessed a smattering of European literature, and was regarded by those who knew him as shrewd and intelligent. Before the mutiny broke out, and while the authorities were temporizing in the hope that the recapture of Delhi would restore peace and order, Nana proposed to strengthen the garrison of Cawnpore by the addition of his own troops. His offer was accepted, and about 300 or 400 men were brought down from his castle at Bithoor, and located near the magazine. At the same time he invited the officers to send their wives and children to Bithoor as a place of safety. On the 4th of June, when the mutiny broke out, Nana placed himself at the head of the rebels, saying "I came in appearance to help the British, but am at heart their mortal enemy." On the following day the 53d and 56th regiments renounced their allegiance, and joined the mutineers. Nana was not slow in proving himself the fitting commander of the rebel force. An alarm having broken out at Futtygurh, a military station situate about 70 miles above Cawnpore, a party of 132 Europeans, consisting of men, women, and children, hurriedly quitted that place in boats, and were proceeding down the river towards Allahabad. Upon arriving off Bithoor, Nana opened fire upon them. An order was then given to board the boats, which being done, the fugitives were seized and dragged to the parade-ground at Cawnpore, where the whole party were barbarously murdered. In the meantime the British force at Cawnpore

Mutiny of
1857.

had taken refuge, together with the women and children, within an intrenched camp under the command of Sir Hugh Wheeler. Here, though besieged by a force 5000 strong, the garrison succeeded in repelling every attack, and, moreover, frequently sallied out from the intrenchments to disperse the rebels. In one of these sorties their gallant leader was severely wounded, and his little band, dispirited by the disaster, worn out by constant watching, enfeebled from want of food, and encumbered moreover with a number of women and children, were induced to surrender, upon receiving the solemn promise of Nana that they should be allowed to withdraw with the whole of the European population to Allahabad. The capitulation was made out on the 1st of July. Upon giving up the treasure, with the guns and ammunition, the garrison with their followers were permitted to embark. But the moment had now arrived for carrying out Nana's meditated treachery. He had never intended that his victims should be allowed to escape. No sooner had the boats loosened from the shore than a fire of artillery was treacherously opened upon them. The boats, with one exception, were then brought back, and the surviving occupants once more landed, when Nana, in spite of his solemn pledge, issued his mandate for the indiscriminate massacre of the male portion of the prisoners. The boat containing General Wheeler does not appear to have been captured until nearly 22 miles below Cawnpore, when it was stopped, and all on board carried prisoners to Nana. Amongst them, besides the veteran commander, who was severely wounded, were Dr Harris and Captain Mackenzie. Their arms had been tied, and thus bound they were led off to execution. All met death bravely. Dr Harris fell saying that his countrymen would revenge his death. Lieutenants Henry Delafosse and Mowbray Thomson, both of the 53d native infantry, had escaped from the advanced boat by swimming. The women and children, in receiving a short respite, were but spared for a worse fate than instant death. For some days they were kept in the most agonizing suspense, and on the eve of the battle of Cawnpore all were barbarously murdered. The number of Europeans thus slaughtered between the 1st and the 15th July amounted in the aggregate to 868, and consisted of 88 officers, 190 rank and file of Her Majesty's 84th foot, 70 ladies, 120 women and children of Her Majesty's 32d foot, and 400 of the European population of the town, including civilians, merchants, shopkeepers, and others. If to these be added the number of fugitives who were intercepted in coming down the river from Futtyghur, the total number butchered by Nana amounts to no less than 1000 Europeans.

The relief of Cawnpore had been intrusted to Brigadier-General Havelock. This officer reached Allahabad on the 30th of June. At this time the relieving force under his command was composed of two European regiments recently withdrawn from Persia—viz., the 64th and the 78th, mustering together 1100 or 1200 bayonets. Moving on from Allahabad on the 4th of July, the general was joined by a small detachment under Major Renaud. With the combined force, which, inclusive of 561 native soldiers, counted in all but 1964 men, the general, on the 12th of July, encountered the rebels, amounting to 3500, with 12 guns, at Futtehpore, situated midway between Cawnpore and Allahabad, and put them to complete route, capturing all their guns. The loss of the British was, perhaps, the lightest that ever attended such signal success. It amounted to no more than 6 sepoys killed, and 8 wounded and missing. General Havelock pursued the enemy in the direction of Cawnpore. On the 15th he again attacked the rebels in their intrenched position, close to the village of Osung, capturing four more of their guns; and on the 16th he signally defeated Nana Sahib in front of Cawnpore. At this place the enemy were posted behind a succession of

villages, where a determined stand was to be made. The fight was most stubborn, and every inch of ground was resolutely disputed during the space of nearly three hours. At length the fate of the day was decided by a flank movement of the 78th Highlanders turning Nana Sahib's left. "I never," says an eye-witness, "saw anything so fine." The men of the 78th went on, with sloped arms, like a wall. Till within 100 yards not a shot was fired. At the word 'charge,' they broke just like an eager pack of hounds, and the village was taken in an instant." Cawnpore now lay open to the British. The rebel chief retired in the direction of Bithoor, blowing up the magazine previous to his retreat. In this engagement the loss of the British was not inconsiderable, amounting to 70 killed and wounded out of a force falling short of 2000 men. This force, however, it must be borne in mind, had been opposed to 6000 mutinous sepoys, armed and disciplined after the English fashion. Upon entering Cawnpore on the following morning, the extent of the frightful catastrophe which had befallen the British garrison and the European residents first became fully known. A wholesale massacre had been perpetrated by Nana Sahib. The site was a paved courtyard. One writer describing the scene, observes:—"The blood was two inches deep upon the pavement; and from the report we got from the residents, it appears that after we had beaten the enemy on the previous evening, the sepoys entered the place where the unhappy victims were confined, killed all the ladies, threw their naked bodies into a well, and hurled down the children alive upon their butchered mothers. I saw it, and it was an awful sight." Long tresses of hair, torn bibles and prayer-books, work-boxes and unfinished work, scattered about the red floor, told too well the harrowing tale. Two or three only of the captives, who had been concealed by their native servants, contrived to escape. The daughter of Sir Hugh Wheeler perished among the victims. This heroic lady, who appears to have inherited the indomitable spirit of her father, is stated to have shot five of the fiends with a revolver before they could get sufficiently near to her to cut her down. Another lady, previous to her death, is declared to have avenged herself by destroying the ruffian who had carried her off, and who probably destined her for outrage. Upon reaching Bithoor in pursuit of the flying enemy, it was found that Nana had just evacuated the village, and the British commander was obliged to content himself with burning the palace of the rebel and bringing away the guns. General Havelock then crossed the Ganges into Oude, on his march to Lucknow, leaving General Neill in charge of Cawnpore. On the 28th July, he twice attacked the rebels, and defeated them in both engagements. Arriving at Oonao on the 29th, he found the place defended by 10,000 of the insurgent troops, including a portion of Nana Sahib's force. The village had been strongly fortified, and every house was loopholed. But the assault of the British was irresistible, and the enemy retreated, leaving behind them their guns. After a halt of four hours, the indefatigable and victorious commander pushed on for Futtehpore Chowraasee, distant about 30 miles from Lucknow. Here a desperate engagement ensued, which resulted in the capture of the town—the rebels withdrawing in the direction of Lucknow. On this occasion the British sustained a loss of 88 killed and wounded. After advancing still nearer to Lucknow, and fighting another battle, in which the British, though as usual victorious, incurred a loss of 85 killed and wounded, General Havelock had the mortification to find that farther progress was for the present impracticable. A body of the rebels, 25,000 strong, were posted in an intrenched position in his front; cholera was making its appearance in his small force, which had been already materially reduced by incessant combats and successive victories. The strength of the little band had indeed been overtaxed.

Mutiny of
1857.

Mutiny of
1857.

It had gained more victories than had ever before been won in so short a time; but its numbers were now reduced below 900 men. In these circumstances, General Havelock, convinced of the impossibility of penetrating the thick masses of the insurgents, deemed it incumbent upon him to pause on his triumphant career, and to fall back upon Cawnpore. A retreat was accordingly commenced. The rebels, taking heart, closely followed in the rear, and advanced as far as Nawabgunge. Here the British commander, nowise daunted by the enemy's superiority of numbers, once more halted to give them battle. Again he was victorious; and, having added two more of the enemy's guns to his previous trophies, he leisurely crossed the Ganges, and on the 13th August rejoined General Neill at Cawnpore. Such a series of gallant exploits forms a brilliant episode in Indian history. The battles of Cawnpore and Oonao lose nothing of their brilliancy, even when compared with the victories of Clive and Wellesley. Having rested for a few days at Cawnpore, General Havelock marched a second time to Bithoor, where it was understood that the rebels, about 4000 strong, were posted with two guns. Here, on the 16th of August, with a force mustering 1300 men and 14 guns, he again encountered them; and, after an obstinate engagement, in which the enemy lost 250 killed and wounded, drove them from their position and captured their guns. The British loss was 14 killed and 30 wounded. General Havelock then determined to return to Cawnpore, there to await the arrival of reinforcements before advancing again upon Lucknow.

Lucknow.

At Lucknow, the capital of Oude, as early as the 3d of May, the men of the 7th regiment of the Oude irregular infantry had mutinied. The city was held by Sir Henry Lawrence, one of the ablest and bravest officers of the Indian army. No time was lost in disarming the regiment. A strict investigation was then instituted, at the close of which it was deemed sufficient to dismiss the greater number of the native officers of the regiment, together with a few of the sepoys, and to overlook the conduct of the remainder. These conciliatory measures failed to produce a better feeling in the other regiments stationed at Lucknow. On the 30th of May an outbreak occurred, when about one-half of the men of the 48th and 71st native infantry, and some few of the 13th native infantry, with two troops of the 7th light cavalry, rose in insurrection. A sharp encounter followed, in which the mutineers sustained considerable loss, but the greater portion contrived to elude pursuit in the direction of Seetapore. The example thus set at Lucknow was promptly followed at every military station throughout the province. The troops at Seetapore mutinied on the 4th of June; those at Fyzabad and Secrora on the 8th; at Sultanpore and Pertaubghur on the 8th; at Pershadeepore on the 10th; and at Burraich and Gonda at dates not given. The regiments at these several stations consisted of two field batteries, two regiments of cavalry, and ten regiments of infantry. From Sultanpore, the 15th Oude irregular cavalry and the 8th irregular infantry, started at once for Delhi. It is worthy of remark, that at Fyzabad the mutiny was marked rather by the generous spirit of Europe, than by the barbarous customs of the East. Here the men after mutinying, actually saluted their officers, and placed the ladies under protection. All the outposts of Oude being thus lost, the mutineers gradually closed in upon Lucknow. The position of Lawrence was now becoming critical. His European force, the only one to be depended upon, was fearfully small. It consisted of 510 men of Her Majesty's 32d foot; and within the intrenchments there were no less than 350 women and children. Three positions only were held by the British,—the Residency, the Muckee Bhawan, and the cantonments. These were greatly strengthened, and the remaining military posts within the city were all abandoned. On the 30th of

Mutiny of
1857.

June, Sir H. Lawrence having learned, by a reconnoissance made on the previous day, that the rebel army were assembling at Chinhutt, about 10 miles from Lucknow, marched thither with 300 of Her Majesty's 32d, 150 of the 13th native infantry, 100 of the 48th and 71st, 125 Sikh horse, 30 mounted Europeans, 300 police, and 11 guns, of which 6 were manned by natives. On reaching the village of Chinhutt, he found the enemy to the number of 15,000 men, with 36 guns prepared to receive him. At the first shot the police went over in a body, and the native gunners, cutting the traces, galloped over to the enemy, or back to Lucknow. The rest of the force displayed prodigies of valour, natives vying with Europeans in daring acts; but overpowered by numbers, the whole body were compelled to retreat to the Residency at Lucknow, leaving 118 European officers and men killed, and 182 natives killed and missing, besides 54 Europeans and 11 natives wounded. The death of Colonel Case, commanding the 32d regiment, who fell at the head of his men, deserves to be recorded. Captain Bassano seeing him fall, went up to assist him. "Leave me to die here," were the words of the wounded hero; "your place is at the head of your company. I have no need of assistance." From the moment the force re-entered the Residency, the siege of that place commenced. On the 2d of July Sir H. Lawrence was wounded by a fragment of a shell; and after suffering amputation of the leg, died on the morning of the 4th, having nominated Major Banks to succeed him as chief commissioner and commandant. On the 20th of July the enemy in vast numbers attempted to storm, but were repulsed with the loss of 1000 men. Next day Major Banks was killed, and was succeeded by Brigadier Inglis, who continued the gallant defence, and repulsed several attempts to storm, of which one on the 10th of August, and another on the 5th of September, were the most spirited. On the 25th of September, Generals Outram and Havelock, with a force originally consisting of 2500 men, cut their way to the Residency, and it becomes requisite, therefore, to return to the operations under Havelock at Cawnpore.

After the second battle of Bithoor, fought on the 16th of August, General Havelock, as above noticed, retraced his steps to Cawnpore, where he expected to be reinforced by fresh succours from Calcutta. Here, on the 14th September he was joined by a force under General Outram, who, though the superior officer, determined with chivalrous generosity to waive his rank on the occasion, and to leave to General Havelock the glory of relieving Lucknow, and rescuing its gallant and enduring garrison. In accordance with this determination, Sir James merely accompanied the force to Lucknow, in his civil capacity, as chief commissioner of Oude, at the same time tendering his military services to the general as a volunteer. On the 19th, General Havelock having formed his little army into two brigades,—of which the first consisted of Her Majesty's 5th fusiliers, the 64th and 84th regiments, the 1st Madras fusiliers, Captain Maude's troop of horse artillery, and 150 European volunteer cavalry; and the second of Her Majesty's 78th Highlanders, the 90th light infantry, Captain Olphert's horse battery, and some irregular horse,—crossed the Ganges into Oude; and on the 21st attacked the rebels at Mungarwar, and drove them from their position, capturing four guns, two of which, together with the colours of the 1st Bengal native infantry, were taken by the volunteer cavalry in a charge headed by Sir James Outram. The loss of the British was trifling.

On the 21st of September the indefatigable general accomplished a march of 14 miles, and one of 20 miles on the 22d, at the termination of which the firing at Lucknow was distinctly heard. A royal salute was then ordered by General Havelock to be fired to announce his approach to the garrison. On the 25th the British force, skirting the city,

Mutiny of
1857.

forced its way to the Residency against enormous numbers of the enemy, and with the loss of 550 officers and men; Brigadier Neill and Colonel Bazeley being among the killed, and Sir J. Outram being wounded.

It was now found that although, by a display of courage which has never been surpassed, the relieving army had made its way to the Residency, it was altogether too weak to remove the besieged, of whom the greater part were sick and wounded, and women and children. On the contrary, Generals Outram and Havelock were now themselves besieged, and their communications even with Alumbagh, where they had left their baggage with a guard of 300 men, were entirely cut off. At a short distance from the Residency, in the palace called the Kaiserbagh, were eight European prisoners, Sir M. Jackson, C.S., and his sister; Captain P. Orr, his wife, and child; Lieutenant Burnes, Sergeant Norton, and Miss Christian; but nothing could be done to relieve them, and all the males were subsequently blown from guns by the rebels. Every day desperate conflicts took place in the inclosure to clear the buildings surrounding the Residency. Sir J. Outram had now taken command; and on the 26th of September ordered a sortie, under Lieutenant Lowe, who cleared the Captan ka Bazar, to the east of the Residency, of the enemy, and took 7 guns, but with the loss of Captain Hughes and 2 men killed, and 2 officers and 8 men wounded. On the 27th a second sortie was made in much greater force against the enemy's Garden battery to the S.W. of the Residency, which succeeded in destroying the battery, but with the loss of 10 killed and 11 wounded. On the 29th three sorties were made, in which Major Simmons, Captain M'Cabe, and a gentleman volunteer of distinguished gallantry, Mr Lucas, were killed, and about 50 others killed and wounded. On the 1st of October Colonel Napier made a very successful sortie, with trifling loss. In this manner such offensive operations as the smallness of General Outram's force would permit were continued till the 16th of November, when a determined and successful sortie was made in the direction of the Kaisarbagh to aid the advance of Sir C. Campbell, who, with a force of about 4000 men, had advanced from Cawnpore upon Lucknow. Simultaneously with the sortie Sir Colin reached the Secunderbagh, a palace on the E. of the city, and S.E. of the Residency, filled with sepoys, and protected by the fire from a large mosque, called Shah Nuijuff, a little to the N., and nearer the Residency. Here a terrific combat raged for three hours, when both places were at length taken, the latter chiefly by means of the 68-pounders of the naval brigade, commanded by Captain Peel. In the Secunderbagh alone 2000 corpses of the enemy were counted. On the 17th other defences of the enemy, between the Residency and the buildings just mentioned, were carried; and on the afternoon of that day, under a heavy fire, Generals Outram and Havelock advanced and met Sir C. Campbell. While Havelock was addressing his deliverers, his son was struck down close to him by a ball, but he continued his harangue, and did not turn to inquire the nature of the wound until he had concluded his address. In these operations 10 officers and 112 men were killed, and 33 officers and 312 men wounded. The long-beleaguered garrison of Lucknow was saved; but the numbers of the enemy were still so great that it was necessary to evacuate the Residency, and retire upon Cawnpore, without making any attempt to take the city. At midnight on the 22d of November the evacuation was noiselessly effected, most part of the effects belonging to the garrison being left behind; and so little was the retreat suspected by the enemy, that they continued to fire on the Residency long after it was deserted, so well had the operation been planned and carried out by General Outram. On the 25th of November General Havelock died of dysentery at Dilkusha, a palace

and park to the S. of the city. On the 27th Sir C. Campbell received intimation from General Windham, whom he had left to defend Cawnpore, that his position had been attacked by overwhelming numbers of the rebels. Sir Colin therefore hastened back to Cawnpore with the utmost speed, and arrived just in time to save the bridge of boats from being destroyed by the enemy, who were in possession of the town, had completely surrounded General Windham, and had brought some guns to bear on the bridge. Their army, estimated at 20,000 men, consisted of the whole Gwalior contingent, comprising four batteries of artillery, two regiments of cavalry, and seven of infantry, and the forces under Nana Sahib and Koer Singh. On the 24th of November the vanguard had approached Cawnpore so close that General Windham resolved to advance to meet them, which he did on the 26th at the Pandu Nadee. After a sharp action he defeated them, and took 3 guns, losing 7 officers and 50 rank and file killed and wounded. Then, instead of retiring upon Cawnpore, he encamped in dangerous ground, amid thick jungle, where he was attacked next day, and, after a murderous conflict, driven into his intrenchments, the enemy occupying Cawnpore, which they plundered, setting fire to many of the public buildings. On the 28th Sir C. Campbell arrived, and extricated General Windham from his perilous position, surrounded by an infuriated enemy, without supplies, and having lost more than 300 of his best officers and men. After keeping the rebels in check until the sick, wounded, and non-combatants had been safely despatched to Allahabad, Sir Colin, on the 6th of December, after skilfully drawing the enemy from their position, advanced on them with irresistible fury, and overthrew them with great slaughter, capturing 16 of their guns, and putting them to headlong flight. He then despatched Brigadier Hope Grant with the cavalry and artillery, who, coming up with the fugitives as they were preparing to cross into Oude, took nearly all their remaining guns, and inflicted a further heavy loss upon them. Sir Colin's subsequent operations and his final victories at Lucknow will be found at the conclusion of this article.

While the events above narrated were occurring at Punjab, Delhi, Lucknow, and Cawnpore, numerous outbreaks and slaughters were taking place in other parts of India. On the 13th of May an outbreak occurred at Ferozepoor, on the left bank of the Sutlej, doubtless prompted by intelligence of the massacre at Meerut. At this station the crisis was manfully met by the British. The two regiments stationed here were the 45th and 57th native infantry. Upon being ordered to march from their cantonments, the 45th broke out into open mutiny. They were at once attacked by Her Majesty's 61st foot and the 10th Bengal light cavalry, which remained staunch, and few escaped from the place. The 57th, upon being reasoned with, gave up their arms. Ferozepoor is about 50 miles south of Lahore, the capital of the Punjab. At Meean Meer, the cantonments of Lahore, were quartered three regiments of native infantry, the 16th, 26th, and 49th, and the 8th light cavalry; and the whole of these, upon the arrival of tidings of the mutiny at Delhi, it was resolved at once to disarm. This being accomplished, the men were moving off to join the disaffected corps at Ferozepoor, but being intercepted by a movement of the British troops, they speedily returned to obedience. The whole business was managed with a degree of tact and discretion which reflects the highest credit on Sir John Lawrence, chief commissioner in the Punjab. Of the disarmed regiments at Lahore, one subsequently mutinied. This was the 26th native infantry, which, on the 30th of July, killed their commanding-officer, and then broke away. The fugitives were chased by the police and some of the new levies, and upwards of 500 were slain, or taken prisoners and executed. At Jullundur the 36th and 61st regiments mu-

1857.

Mutiny of
1857.

tinied on the 4th of June, and with a few men of the 6th light cavalry proceeded to Phillour, where they were joined by the 3d native infantry. These corps crossed the Sutlej and entered Loodiana, whence, being driven out by a detachment of Her Majesty's 8th foot, they made their way to Delhi. Symptoms of disaffection had also been manifested in the 51st and 55th regiments stationed at Peshawur, and some of the men had been discharged about the end of May. The 51st subsequently mutinied at Peshawur, and the latter at Huzzara. The 51st had been disarmed, and swift retribution overtook their treachery, nearly the whole regiment being cut up, or taken prisoners and executed. The 55th were attacked and broken, and a large number taken prisoners were executed at Huzzara. A remnant escaped, and took refuge with the predatory Affghans of the frontiers; but although at first received as friends, they are said to have been forcibly converted to Mohammedanism, and sold as slaves. At Mooltan two native regiments were disarmed by Brigadier Chamberlain. Sealkote, another military station in the Punjab, took an active part in the mutiny. The 35th regiment of native infantry, part of the illustrious garrison of Jellalabad, proceeding from Sealkote to Delhi, were believed to be wavering in their fidelity, and were disarmed. The 14th native infantry, which had mutinied at Jhelum, had been completely broken, with the loss, however, of 50 Europeans of Her Majesty's 24th regiment killed and wounded, besides 3 officers; but a small remnant escaping to Sealkote, were there joined by the 46th regiment, and a wing of the 9th light cavalry. The main body of these mutineers was overtaken by General Nicholson on the 16th of July, and completely cut up. In the meantime a moveable column had been organized by General Reed, in concert with Brigadiers Chamberlain, Cotton, Edwardes, and Nicholson; and mutiny, wherever manifesting itself in the Punjab, was speedily quelled and put down with a strong hand. Thus, not only did Sir John Lawrence suppress insurrection in his own province, but contributed also, in a great degree, to the success at Delhi, by forwarding large and timely reinforcements to the besieging army.

Allygurh.

Allygurh, an important post, as commanding the communications up and down the country, had been garrisoned by four companies of the 9th native infantry, the men of which had hitherto conducted themselves with steadiness. On the 20th of May these companies rose against their officers, who were thus compelled to abandon the station. A portion of the same regiment, which was quartered at Mynpoorie, mutinied on the 22d of May; but by the tact and admirable conduct of one of their officers, Lieutenant De Kantzow, the men were kept back from acts of violence, and finally quitted the station to join their comrades at Allygurh, *en route* to Delhi.

Nusseera-
bad.

At Nusseerabad, in the province of Ajmere, the 15th and 30th regiments of native infantry, and the 2d company of the 7th battalion Bengal artillery, mutinied on the 28th of May, and beat off with loss a portion of the 1st regiment of Bombay light cavalry (lancers), who gallantly charged the guns. In this engagement Captain Spottiswoode and Cornet Newberry were killed, and Captain Hardy and Lieutenant Jack wounded. Colonel Penney, commanding the 1st light cavalry, was killed by a fall from his horse. The rebels marched with colours flying and bands playing to Delhi. Subsequently a portion of the 12th Bombay native infantry mutinied at Nusseerabad on the 10th of August, and was disarmed.

Hansi,
Hissar,
and Sirsa.

On the 29th of May the Hurreenah battalion and 4th irregular cavalry, stationed at Hansi and Hissar, to the north-west of Delhi, mutinied and massacred a number of Europeans. Many of the civil and military officers effected their escape. The gallant general, Van Cortlandt, who so signally distinguished himself in the Mooltan campaign, march-

ing from the north-west, had two engagements with the rebels at Sirsa, defeating them in each instance with severe loss.

Mutiny of
1857.

At Bareilly the 18th and 68th native infantry, and the 8th irregular cavalry, rose *en masse* on the 31st of May. The outbreak appears to have been concerted for a fixed hour at a given signal. Brigadier Sibbald was killed. Many of the European residents and civil servants of the Company were massacred. Fortunately the ladies had quitted the station some days earlier for that of Nynee Tal. Among the victims were the two judges of Bareilly, Mr Raikes and Mr Robinson. These two gentlemen were arraigned before one of the native judges. It does not appear of what they were accused, but a mock trial ensued, when they were found guilty and beheaded. A number of half-castes and native Christians, amounting to no less than ninety individuals, were also dragged to the church and there butchered.

Shahjehanpore, situated 50 miles to the south-east of Bareilly, was the scene of a more striking tragedy enacted on the same day. Here the Christian residents were at church, when the 28th regiment, after cutting down their officers, surrounded the edifice, and massacred the whole congregation.

Agra also added to its celebrity by the heroic conduct of its garrison during the military revolt. An escort of treasure, proceeding from this place to Muttra about the middle of May, and consisting of two companies of the 44th and 67th native infantry, shot their officers, and decamped with the booty. Intelligence of the atrocity being conveyed to Agra, the two regiments on the 31st of May were ordered to parade and deliver up their arms. No hesitation was evinced by the men in obeying the mandate. From this time all was quiet for several weeks. But at the commencement of July the city was menaced by the 72d native infantry, a wing of the 7th light cavalry, and the 4th troop 1st battalion horse artillery, who, their ranks being swelled by bodies of malcontents, had marched to Futteypore Sikri from Neemuch, a cantonment distant 300 miles. At their approach the European inhabitants took refuge within the fort. The garrison there consisted of the East India Company's 3d regiment of European infantry, numbering, with the artillery, 650 men, besides 500 volunteers, foot and horse. On Sunday, the 5th of July, about 500 of this garrison,—it being known that the enemy were within 3 miles of the station,—boldly issued forth to confront the enemy. An obstinate battle ensued, and the rebels were dislodged from their position; when, the ammunition of the British force falling short, it was compelled to retreat. The English loss amounted to 49 Europeans killed, and 92 wounded. The spirit and gallantry displayed on the occasion seems to have had one good result, in securing the fort from attack or investment. About 5000 Europeans, including the garrison, had taken refuge within its precincts. The native troops stationed at Agra, consisting of the Kotah contingent and the Kerowlee horse, mutinied before the battle, and joined the rebels. Some weeks previous to these events, *i.e.*, on the 25th of May, a proclamation had been issued by the lieutenant-governor of Agra, offering pardon to all mutineers who should lay down their arms. This proclamation was disapproved by the government, and another substituted. Subsequently the rebels were dispersed. On the 24th of August a detachment from the fort, under Major Montgomery, consisting of about 200 men, encountered a strong body of the insurgents of the Doab, posted in the inclosed garden of Maun Singh, between Hatrass and Allygurh, and drove them back with great slaughter in the direction of Allygurh.

At Benares, from the moment of the outbreak, great uneasiness had been felt, and when Colonel Neill reached that city with the 1st Madras fusiliers on the 3d of June, matters were in a very critical state. On the following

Benares.

Mutiny of
1857.

day a report reached the city that the 17th regiment of native infantry had broken out into open mutiny, and attacked an escort of treasure at Azimgurh, situated 80 miles north of Benares. Upon this it was thought advisable to disarm the 37th regiment of native infantry, in which some excitement had been displayed. The regiment being ordered on parade, Colonel Neill called upon the men to lay down their arms. This was answered by a fire upon the British, which was immediately returned by the artillery and Europeans. The Sikh regiment and the irregular cavalry joined the mutineers. Upon observing the disaffection of the Sikhs, the artillery opened fire upon them, and broke them, though they charged up to the muzzles of the guns. The expulsion of the 37th from the lines was then effected, the mutineers taking the route of Jaunpore. After doing good service at Benares, Colonel Neill pushed on to Allahabad, where he arrived on the 11th of June, in time to save the fort. Here the 6th regiment of native infantry, which had rendered itself conspicuous by declarations of loyalty, mutinied on the 4th of June. The mutineers were joined by three troops of Oude irregular cavalry, and turned upon their officers, thirteen of whom they cut down. The remainder, with several civilians, took refuge in the fort, while the town was occupied by the insurgents; an influential Moulvie having set up his standard in the immediate vicinity, and gathered around him the elements of rapine and disorder. Colonel Neill found the place closely invested by the rebels. These he attacked on the 13th and 15th of June, on which last-mentioned day the enemy, beaten on all points, abandoned the city. On the 12th of July Colonel Neill was promoted to the rank of brigadier-general; and on the 16th, having handed over the command of the Allahabad garrison to Captain Hay of the 78th Highlanders, proceeded to Cawnpore to join General Havelock. The death of this gallant officer at Lucknow has been already noticed.

Gwalior.

The Gwalior contingent, a body of native troops paid by Scindia, but commanded by British officers, revolted on the 16th of June, in spite of the efforts made by the Maharajah, through whose aid alone the British officers escaped. From that time to the middle of November this powerful body of rebels remained inactive in the neighbourhood of Gwalior, being kept in check by Scindia, who called out his feudatories for that purpose. Several times a battle was on the eve of being fought, in which the superior discipline of the rebels would have probably given them the advantage. Had they succeeded, or had Scindia been less warm in the English cause, it cannot be doubted that the mutinous contingent would have agreed to the proposal of the Indore rebels and marched on Delhi, in which case the British besieging army would have been in imminent peril. Foiled, however, by the opposition of Scindia, the Gwalior contingent at length, about November, advanced towards Calpee, and thence, on the 24th of that month, marched on Cawnpore, where they engaged and defeated General Windham, but were subsequently routed, as mentioned above, by Sir Colin Campbell. They, nevertheless, still continued to hang about Calpee; and on one or two occasions skirmished sharply with the English advanced posts in that direction.

Indore.

Holkar's contingent rose on the 1st of July, and attacked the government British Residency, which they destroyed, and killed several officers and many persons connected with the English government. Most of the Indore officials and Europeans escaped to Sehore, from whence they arrived safely at Hoshungabad. The main body of these mutineers marched to Gwalior, where they vainly endeavoured to prevail on the Gwalior contingent to join them in an advance on Delhi. At last, on the 5th of September, they proceeded to Dholpore, about 30 miles from Agra, at the point where the road from Delhi to Bombay crosses the Chumbul. Fortunate

it was that Delhi had fallen ere this great force of rebels could reach it. Colonel Greathed's column, which had been despatched towards Agra as soon as Delhi was completely occupied, after dispersing the Jhansi rebels in a sharp action at Bolundshuhur on the 27th of September, and blowing up the fort of Malagurh on the 29th, reached Agra on the 10th of October early in the morning. The weary troops had scarce begun to encamp when they were charged by the cavalry of the Indore rebels, whose guns opened on them at the same time. The English suffered some loss, and had a gun captured before they could form their ranks to resist this surprise. The Sikh horse were the first to charge the enemy, and they were followed by the 9th lancers, who charged in their shirt sleeves. The English guns then opened, and, after a fierce engagement of two hours, the rebels were routed with great slaughter, with the loss of thirteen guns and all their camp equipage. From the date of this overthrow Holkar's contingent never again formed a compact body. Indore itself was kept from joining fully in the rebellion, mainly through the zealous efforts of the young Prince Holkar, who throughout showed the most unshaken fidelity to the British. On the 15th of December the Malwah field force, under Brigadier Stewart, arrived in the city, and disarmed the malcontents, on many of whom summary justice was executed.

Mutiny of
1857.

At Jhansi the troops, consisting of a wing of the 12th Jhansi native infantry and some irregular cavalry, mutinied on the 5th of June, and a large number of Europeans, men, women, and children, were horribly murdered. The rebels marched off to Delhi. Upon the recapture of the city by the British on the 21st September, the Jhansi insurgents evacuated the place, and took the road to Bolundshuhur, where, on the 27th, as above stated, they were attacked by the pursuing column under Colonel Greathed, and completely routed.

At Saugor, in Central India, although the majority of the Saugor troops participated in the general spirit of mutiny, a remarkable instance of loyalty was displayed by one regiment. On the 3d of July, the 42d native infantry, and part of the 3d irregular cavalry, mutinied, and called upon the 31st regiment to join them. The latter regiment, deprived of its European officers, who had taken refuge in the fort, nevertheless behaved most loyally, drove the mutineers out of the station, retook a large signal gun and six elephants, which they restored to the authorities. The defeated rebels were, however, joined by large bodies of Boondelas and other marauders, and soon after completely invested Saugor, which remained in a state of siege and in extreme danger till the 3d of February 1858, when it was relieved by General Sir Hugh Rose, commanding the Nerbudda field force.

Though the spirit of disloyalty was known to be all but universal throughout the Bengal army, three regiments of native infantry continued to be maintained in full force at Dinapore. These were the 7th, 8th, and 40th. A deputation of merchants had waited upon the governor-general, entreating that these regiments might be disarmed; but the reply had been, that the government had every confidence in the fidelity of the men. Shortly afterwards, however, the symptoms of mutiny became unmistakable, and on the 25th of July the three regiments threw off their allegiance, and broke out in insurrection. At this time Her Majesty's 10th foot, and part of Her Majesty's 37th regiment, with an European field-battery, were quartered at Dinapore. Nevertheless, by the mismanagement of General Lloyd, in command of the station, and owing to his physical unfitness for his duties, the three mutinous regiments were allowed to cross the Soane river, and to escape with little loss to Arrah, distant twenty-five miles west of Dinapore. Here Mr Wake, the magistrate of the district, with 11 other Europeans and 45 Sikhs had taken refuge within a small bungalow, which had been previously fortified. The build-

Mutiny of
1857.

ing was forthwith surrounded by the insurgents. This being made known at Dinapore, a detachment composed of 350 men of the 10th and 37th regiments was despatched by boats for the relief of the little band; but being landed by night, under the direction of treacherous guides, the party fell into an ambuscade, and were driven back with a loss of more than half their number killed and wounded. The disaster was in some degree retrieved by the heroic defence of the besieged garrison. These succeeded in holding the rebels at bay during seven days, until the 8th of August, when, after the failure of the expedition from Dinapore, they were relieved by Major Vincent Eyre, of Caubul celebrity, who, with a detachment of 200 men and three guns from Buxar, dispersed a force of 3000 insurgents, headed by a native rajah, Kowur Singh, of Jugdeespore, with three pieces of artillery. The particulars of this romantic defence are thus given by Mr Wake, the magistrate of Shahabad:—"During the entire siege, which lasted seven days, every possible stratagem was practised against us. The cannons were fired as frequently as they could prepare shot, with which they were at first unprovided, and incessant assaults were made upon the bungalow. Not only did our Sikhs behave with perfect coolness and patience, but their untiring labour met and prevented every threatened disaster. Water began to run short—a well 18 feet by 4 was dug in less than twelve hours; the rebels raised a barricade on the top of the opposite house—our own grew in the same proportion; a shot shook a weak place in our defence—the place was made twice as strong as before; we began to feel the want of animal food and short allowance of grain—a sally was made at night, and four sheep brought in; and finally, when we ascertained beyond a doubt that the enemy were undermining us, a countermine was quickly dug. On the 30th, the troops sent to our relief from Dinapore were attacked and beaten back close to the entrance of the town. On the next day the rebels returned, and telling us that they had annihilated our relief, offered the Sikhs and the women and children (of whom there were none with us) their lives and liberty, if they would give up the government officers. August the 1st, we were all offered our lives, and leave to go to Calcutta, if we would give up our arms. On the 2d, the greater part of the sepoys went out to meet Major Eyre's field force, and on their being soundly thrashed, the rest of them deserted the station; and that night we went out, and found their mine had reached our foundations, and a canvass tube filled with gunpowder was lying handy to blow us up; in which, however, I do not think they would have succeeded, as their powder was bad, and another stroke of the pick would have broken into our countermine. We also brought in the one gun which they had left on the top of the opposite house. During the whole siege, only one man, a Sikh, was severely wounded, though two or three got scratches and blows from splinters and bricks." The mutineers, driven from Arrah, retreated in the direction of Jugdeespore, whither they were pursued by a detachment of the 10th foot. Here the men of that regiment gloriously avenged the slaughter of their comrades at Arrah. After a contest which lasted for upwards of two hours, Jugdeespore fell into their hands. No less than 400 of the rebels were cut down, and the remainder completely routed. General Lloyd being removed from his post, Sir James Outram succeeded to the command of Dinapore, but shortly after moved up towards Oude.

Jubbulpore.

Among the latest revolts was that of the 52d native infantry, which mutinied and quitted Jubbulpore, a station 111 miles S.E. of Saugor, with the view of effecting a junction with the Dinapore rebels. The insurgents were met near the fort of Saugor by the column of Madras troops from Kamptee, and defeated, with a loss of 150 killed. Lieutenant Macgregor, who had been detained by the regiment

as a kind of hostage, was murdered by the rebels. His body was found by the British covered with wounds. Mutiny of 1857.

At the small town of Nagode or Nagound, on the road from Saugor to Allahabad, and about 30 miles to the N.W. of Rewah, was stationed the 50th Bengal native infantry. This corps mutinied, but without slaughtering its officers, not long after the outbreaks at Saugor and Jubbulpore; and thus the circle of rebellion was completed in Bundelcund. The rajahs of Saugor and Shahgurb, and the rani of Jhansi, aided the insurgents with all their power. The rajah of Rewah remained faithful, though his troops were disaffected.

On the 21st of August a detachment of the Jodhpore legion, stationed at Aboo, rose, plundered the bazaar, and attempted to murder some invalids of Her Majesty's 83d regiment, but were repelled from their barracks with loss. They wounded Mr A. Lawrence, son of General G. Lawrence, and, descending the mountain, plundered the village of Anadra at the foot of it, and then proceeding to the stations where the other parts of the legion were, induced them to join. On the 1st of September General Lawrence marched from Ajmere to meet them, and on the 18th came upon them at Awah, and succeeded in driving them from their position outside the town, but finding this too strong to be attacked, was compelled to retire. Here Captain Monk Mason, who had pushed on from Palee to join General Lawrence, was killed in the attempt. About this time the chiefs of Dhar, Mundesore, and Amjheera, joined in the rebellion; and on the 19th and 20th of September a sharp action was fought at Neembhera, about 20 miles N.W. of Neemuch, in which the 12th Bombay native infantry, and the 2d Bombay cavalry, distinguished themselves. The place was taken with the loss of one European killed, and 16 natives killed or wounded. The Jodhpore legion was subsequently completely routed at Narnoul, 86 miles S. of Hansi, by Colonel Gerrard, who was killed in the action. Five officers were wounded, and the total of killed and wounded was 70.

At Kotah, the capital of the Rajpoot state of that name, situated on the right bank of the Chumbul, 195 miles S.W. of Agra, the forces of the rajah, consisting of 2140 infantry, 710 cavalry, and 600 artillerymen, rose against his authority, and in rebellion against British supremacy, on the 15th of October, and murdered the political agent, Major Burton of the 40th Bengal native infantry, with his two sons. They then plundered the Residency and set fire to it.

Besides these principal outbreaks, many lesser risings and mutinies of single corps, or detachments of corps, took place in other various parts of India. Thus the Ramgurbh battalion mutinied near Sherghotty, and on the 29th of September were met and routed by Major English with a detachment of the 53d regiment and some Sikhs. The 32d native infantry rose at Deogurbh in the south-west districts, and killed Lieutenant Cooper, Mr Ronald, and some others; the 34th at Chittagong, and the 73d at Dacca and Julpigoree, also mutinied so late even as November 1857, but the defection of these corps produced only local disturbance, and added little or nothing to the danger and magnitude of the general revolt. In the meantime, the Madras army, with the exception of the 8th cavalry, which refused to proceed on service to Bengal, and was consequently disarmed, and a few irregular troops at Nagpore, continued faithful and aided greatly in the suppression of the revolt. The principal native ruler in Southern India, the Nizam, threw the whole weight of his influence into the scale in favour of the British; and his minister, Salar Jung, a nobleman of European energy, courage, and abilities, crushed a desperate attempt of the fanatical Rohillas to raise the standard of rebellion at Hyderabad. In the Bombay army, where there were 15,000 soldiers, recruited from Oude and the adjacent provinces, the case was different. On the evening of the

Mutiny of
1857.

31st of July, 167 men of the 27th Bombay native infantry rose at Kolapore, in the South Mahratta country, and murdered three of their officers, and carried off 37,000 rupees from the treasury. They were shortly afterwards attacked by Lieutenant Kerr, with a body of the South Mahratta irregular horse, and dispersed or destroyed. The fugitives perished in the jungles of want, or were killed by the villagers. On the 10th of August a trooper of the 1st Bombay lancers attempted to raise an *émeute* at Nusseerabad, and was for a time protected by the 12th native infantry, but at length shot. About the same time a small part of the 2d Bombay cavalry mutinied at Neemuch, and were not overpowered without a struggle, in which four Europeans lost their lives. Plots were also discovered in the 2d grenadiers at Ahmedabad, and the 29th native infantry at Belgaum; and on the 20th of August the havildar major of the latter regiment, and some others, were executed. At Bombay the 10th native infantry were discovered to be in a disaffected state; and a soldier of that corps, and one of the marine battalion, were blown from guns. But it was in Sindh that the most extensive conspiracy was formed; and but for the fidelity of Jacob's horse, and the admirable management of the commissioner, Mr Frere, the whole of that province would have been in a blaze. At Kurrachee the 21st Bombay native infantry were disarmed, and a considerable number of sepoys executed; at Shikarpore and Hyderabad there were attempts at a rising; and at the former place the Bengal artillerymen seized the guns, and kept up a fire on cantonments for some time. These particulars suffice to prove the alarming state of India when the European reinforcements from England began to arrive. It remains now to show how these were made available for the extinction of the revolt.

Measures
for sup-
pressing
the revolt.

Between June the 18th and the end of November 1857, ninety-four large transports were despatched from England, having on board 34,481 European soldiers to reinforce the royal army in India. In addition to these, 900 men were despatched overland; and several regiments were drawn from the Cape, Ceylon, and the Mauritius, and also from the China expedition, whence also was furnished a formidable naval brigade, the men of which served 68-pounder guns with terrible effect in the storming of Lucknow. In the beginning of November the bulk of these reinforcements began to arrive, and in the first fortnight of that month 8000 men were landed at Calcutta alone. Thus along the Ganges a stream of reinforcements was constantly flowing up, enabling the commander-in-chief to reduce Lower Bengal to order, garrison the chief places, and prepare a powerful army for the capture of Lucknow and the complete conquest of Oude. At the same time Sir J. Lawrence was actively engaged in levying new Sikh troops and despatching them to the south; while Jung Bahadur, the regent of Nepal, sending forward several thousand Gorkhas to the aid of the British, prepared to descend from the hills into Oude with 10,000 more. At Madras and Bombay, as fresh European regiments arrived, those already in the presidencies were pushed up towards Central India, and there formed into columns, which gradually swept the rebels towards the east, and co-operated with the columns from the Delhi and Punjab armies, which, advancing southward, cleared the Doab and Rohilcund, and drove the insurgents into Oude, where they were stopped by Sir C. Campbell and the main army. Turning to the operations of the subsidiary columns during the close of 1857, and taking that of Colonel Greathed first, it may be briefly noticed, that after the defeat of the Indore rebels on the 10th of October, this force halted a few days at Agra, and reached Mynpooree, 71½ miles to the east of Agra, on the 19th; and on the day previous Brigadier Grant took command from Colonel Greathed. The guns and treasure of the rajah, who had fled with the rebels, were here cap-

tured, and the fort was blown up. On the 23d the column arrived at Kanouj, and there falling in with a body of the Delhi fugitives, killed 200 of them, and captured five guns, with the loss of one officer and two privates wounded. On the 26th the column reached Cawnpore, whence, its losses being recruited by fresh troops, and having been made up to 3460 men, with twenty guns, it moved on towards Lucknow, and arrived at Nawabgunge, near that city, on the 1st of November. From this date its operations merge in those of the main army.

Mutiny of
1857.

In the meantime, the districts west of Delhi were swept by a column under Brigadier Showers, who, on October the 2d, captured Rewarec, 50 miles S.W. of Delhi, the town of a rebel rajah, who fled, leaving twelve guns loaded on the ramparts of his fort. On the 12th Brigadier Showers reached Jhajhar, once the capital of the adventurer George Thomas, but now of a rebel nawab, who was made prisoner on the 17th, and subsequently hanged at Delhi. The column then moved to Dadree, cutting to pieces some small parties of rebels on the way, and thence to Kanound, where fourteen guns and considerable treasure and stores were taken. On the 31st of the same month a detachment of this column cut up a body of Mewatties on the heights near Sona, in the Goorgaon district. The column returned to Delhi on the 9th of November, and immediately after moved out again to Meerut, *en route* for Bewar.

From Madras a strong column having assembled at Kurnool under Brigadier Whitlock, moved upon Jubbulpore, and on the 15th of December advanced from that town into the Saugor territory, quieting the disturbed districts as it proceeded, and sending on two regiments of cavalry to clear the way to Benares. The advance of this column was greatly facilitated by the brilliant successes of Captain Osborn, the political agent at Rewah, and Lieutenant-Colonel Hinde, who, with the forces of the rajahs of Punnah and Rewah, and some levies raised in Bundelcund, defeated several bodies of insurgents, and captured the strong fort of Bijrajooguih, the killadar of which place, and ninety-three other prisoners, were shot by command of Brigadier Whitlock. Simultaneously almost with the successful operations of the last-named officers, an alarming outbreak of the wild tribes in Sumbulpore, a large expanse of jungly country directly south of the region in which the column of Brigadier Whitlock was moving, was put down by Major Bates of the 40th Madras native infantry, and Captain Wood, commanding a squadron of the Nagpore irregular cavalry. On the 30th of December Captain Wood, with 73 horsemen and 200 infantry of the 40th native infantry and Ramgurh battalion, encountered a body of the rebels near Sumbulpore, and killed fifty-three and dispersed the rest. Captain Wood, who killed three of the enemy with his own hand, was wounded, with Dr Winslow and nine privates. These rebels had previously murdered Dr Moore not far from the spot where they were defeated. Another body of insurgents was shortly afterwards routed with great slaughter by Major Bates in the same district. Madras troops were likewise successfully engaged some weeks later in suppressing a rebellion raised by the rajah of Shorapore, a small principality in the S.W. angle of the Nizam's territories. On the 7th of February the troops of the rajah were defeated near his chief town by a small Madras column, with trifling loss to the English; but Captain Newbery of the 8th Madras cavalry was killed, and Lieutenant Stewart of the same corps wounded. Shorapore was occupied next day by Colonel Malcolm, with the South Mahratta horse; and the rajah himself was made prisoner at Hyderabad, whither he had fled.

From the Bombay side a column called the Malwah field force, consisting of the 14th light dragoons, Her Majesty's 86th foot, the 3d Bombay cavalry, the 25th native infantry, some Bombay artillery, and a strong force of the Nizam's

Bombay
army.

Mutiny of
1857.

contingent, had been organized under Brigadier Stewart of the 6th native infantry, for operations in Central India. On the 22d of October this column defeated a body of rebels near Dhar; and on the 1st of November took that strong place, the fort being one of the strongest in India. After the battery had opened for four days, an advance was made to the breach, when the fort was found to be evacuated. A treasure of nearly half a million was here captured. On the 8th Brigadier Stewart marched north towards Mehidpore, when an army of rebels under Heera Singh, formerly a jemidar in the Nagpore cavalry, had, with the aid of the Mehidpore contingent, which mutinied as they approached, committed great havoc, and killed Major Timms, Captain Mills, Dr Carey, and several other Europeans, as well as 150 of the contingent who remained staunch to the British. On the 13th Major Orr, with the 1st, 3d, and 4th Nizam's cavalry, attached to the Malwah field force, came up with Heera Singh, and made a most brilliant and successful charge, retaking all the guns and stores just captured from the Mehidpore contingent. The rebels were pursued to a village ten miles from Mundesore, where their supports showed themselves in great strength. On the 21st the whole column, of which Major Orr's cavalry formed part, was attacked by the Mundesore rebels, numbering about 8000 men, who were driven back into the town with heavy loss. On the 23d the column defeated Heera Singh at the village of Gooraria. The 14th dragoons captured five guns on the enemy's left centre. Lieutenant Redmayne of that corps was killed, and seven officers were wounded, and 68 rank and file killed and wounded. On the night of the 24th the rebels evacuated Mundesore. These rebels had besieged Neemuch for the three weeks previous to the arrival of the Malwah field force, and on the 21st had attempted to carry it by escalade, but were repulsed with loss. The casualties on the English side were two European officers and four sepoy wounded. The 12th Bombay native infantry here particularly distinguished themselves. In a battle fought, however, at Jeerun, near Neemuch, on the 24th of the previous month, the English garrison of that town had sustained severe losses. On that occasion Captain Tucker of the 2d Bombay cavalry, and Captain Reade of Her Majesty's 83d foot, were killed, five officers were wounded, and other casualties were numerous. The Malwah field force now made a long halt at Mundesore, where many of the rebels were executed. On the 2d of December it moved south to Indore, which it reached on the 15th; and next day Sir R. Hamilton, the governor-general's agent for Central India, and General Sir Hugh Rose, arrived there, and Holkar's mutinous troops were forthwith disarmed, and numerous executions took place. General Rose having gained the chief command of this column, which was now called the Nerbudda field force, proceeded to Sehore, a town in Bhopal, 132 miles S.W. of Saugor. Arriving here on the 10th of January 1858, he disarmed the mutinous Bhopal contingent stationed at Sehore, and caused 150 of them to be executed. He had now with him the 14th and 17th dragoons, and the 3d Bombay lancers, Her Majesty's 86th foot, the 3d Bombay European regiment, and a very powerful force of artillery, sappers and miners, and engineers. On the 26th the general laid siege to the strong fort of Ratgurrh, which was taken on the 29th, many of the rebels escaping down the precipitous rocks. The day previous an insurgent force which attempted to relieve the garrison was defeated, and driven across the river, by Captain Hare with the Hyderabad contingent. A pretender, who had assumed the title of a prince of the house of Timour, named Muhammed Fazl Khan, was here taken and hung with another chief over the gate. On the 30th Sir H. Rose marched for Saugor, and at the first stage from Ratgurrh, drove a body of rebels from some difficult ground. Here

VOL. XVI.

Mutiny of
1857.

Captain Neville of the royal engineers, aide-de-camp to Sir H. Rose, was killed. On the 3d of February Sir Hugh reached Saugor and relieved the garrison, which had been besieged since July of the previous year. Twenty rebels were executed here.

On the 3d of March Sir H. Rose, moving on Jhansi, forced the Mudianpore Pass, with the loss to the British of 20 killed and wounded.

Early in January 1858 a strong column, under Brigadier Roberts, prepared to move from Deesa in Gujerat into Rajpootana. On the morning of the 6th, 200 men of the 10th Bombay native infantry, 100 of Her Majesty's 95th regiment, 2 guns, 30 men of Captain Aitken's battery, and 20 of the royal sappers and miners, under command of Major Raines of the 95th, went forward to attack the village of Rowah, 9 miles from Deesa. It was found strongly fortified, but the infantry gallantly stormed it. Three British officers were wounded, and several men. Gold and silver coins to the value of L.5000 were found among the ruins of the village. On the 10th Major Raines, having sent back his sick and wounded to Deesa, and having received reinforcements, advanced towards Awah, his column now consisting of the 8th hussars, 1st Bombay lancers and 2d cavalry, Her Majesty's 72d Highlanders, and 96th and 51st regiments, with a detachment of the 83d and the royal engineers, the 1st and 2d native infantry, Captain Aitken's battery, 2 troops of horse artillery, and a siege train. On the 19th the column was joined at Jaitpoora, 2 miles from Awah, by two companies of the 83d, a battery of foot artillery, 600 Sindh horse, two squadrons of the 1st lancers, and part of the 12th native infantry, under Colonel Holmes of the latter regiment, who took command of the whole force. On the night of the 23d this column captured Awah, one of the strongest towns in Rajpootana, taking 16 guns and 170 prisoners, of whom 25 were executed forthwith. On the 1st of February General Roberts marched from Deesa to join Colonel Holmes, having with him some sappers and miners, a wing of the 9th regiment, and some of the 2d cavalry, and having effected a junction, the whole column, 7000 strong, with 30 guns, marched towards Kotah, through the pass of Bharoondurrah.

In the meantime, the commander-in-chief was busily engaged in preparing for the final reduction of Oude and the capture of Lucknow. After the complete route of the Gwalior rebels, and their flight across the river into Oude, or westward to Kalpee, Sir C. Campbell despatched a column under Brigadier Walpole to clear the Lower Doab, and make its way to Etawah. He himself, leaving three regiments at Cawnpore with instructions to put that place in a state of defence by digging rifle-pits, throwing up earthworks, and levelling buildings that might yield cover to an enemy, moved with the main army upon Furruckabad. This place, the capital of the district so called, and distant from Agra 90 miles, from Lucknow 95, is on the left bank of the Ganges, while the British cantonment of Futtygurrh lies about 3 miles to the west, on the right bank of the river. Both places were occupied in great force by the rebels; and the nawab had taken a leading part in the insurrection, and by the murder of a great number of Europeans had made himself only less infamously prominent than Nana Sahib. As Sir C. Campbell approached, the nawab received an accession of strength from Etawah, the rebels at that place deserting it on the 29th of December, when Brigadier Walpole entered, and flying to Furruckabad. On the 20th of January Sir Colin came to a place one march from Furruckabad, where a bridge over the Kalee Nadee had to be repaired. The working parties were attacked by about 5000 rebels, who were, however, quickly put to flight, with the loss of all their guns, seven in number. Here a most gallant officer, Lieutenant Younghusband, of the 5th Punjab

2 R

Mutiny of
1857.

cavalry, was wounded mortally, and Lieutenant Maxwell, of the Bengal artillery, severely. The next day Sir Colin occupied Furruckabad, which was evacuated by the enemy, the nawab leaving his guns and stores behind him. A column from Delhi, under Colonel Seaton, arrived at Futtygurh at the same time. On the 29th of December Captain Hodson, of the irregular cavalry, had brought despatches from this column to Sir Colin, riding 90 miles across a country overrun with rebels. In this hazardous exploit three of his escort were killed, and a few wounded. On the 13th of January Brigadier Walpole, with his brigade, was moved forward to repair a bridge over the Ram Gunga; and as a powerful force of the enemy assembled to oppose him on the opposite bank, reinforcements were sent out to him on the 15th. On the 26th a sharp action was fought between a force under Brigadier Hope, and 5000 of the rebels, with four guns, who had crossed the river at Mhow, 18 miles from Furruckabad. Captain Hodson was severely wounded, and his second in command, Lieutenant Macdougall, killed. Captain Steel of the 9th lancers, and Lieutenant Gough of the 3d Bengal cavalry, were also wounded; and 13 men and Dr Fairweather of the 4th Punjabees, and 10 men of Her Majesty's 53d regiment, were killed or wounded by the explosion of one of the enemy's tumbrils. On the 1st of February the commander-in-chief, leaving a brigade to watch the Rohilcund rebels, broke up his camp from Futtygurh and descended upon Cawnpore. He himself rapidly passed through the place on the 4th, reached Allahabad on the 8th, where he had an interview with the governor-general, who was now on his way to the seat of war. The same night he returned to Cawnpore, where, till the beginning of March, he was employed in superintending the concentration of stores and troops for the advance on Lucknow. On the 3d of February the 88th regiment, with two guns and some Sikh horse, despatched to watch the Kalpee rebels, arrived at Bhognipore, 5 miles from Kalpee. Next morning they were attacked by the rebels from the latter place, consisting of part of the Gwalior contingent, and the 32d and 40th native infantry. The enemy first attacked the picquet of Captain Thomson, who commanded the Sikh horse. He bravely held his ground until reinforced, when the enemy were repulsed, and pursued to within a mile of Kalpec. Captain Thomson was wounded, and six men, the former severely. On the 7th of February Mr A. Hume of the civil service, with 400 matchlock-men, and a corps of irregular cavalry under Captain W. Alexander and Mr Maconochie, moved out from Etawah 22 miles to Anundram, where about 800 rebels occupied a strong position with one gun. Mr Hume gallantly led the storming party, and put the rebels to flight, who were then sabred by the cavalry. The enemy left 25 dead on the field; their gun was taken, and 6 prisoners, who were hanged. Mr Hume's party lost 38 killed and wounded. About a month previous to this the Bareilly rebels despatched three columns, two to attack Nynce Tal, and the third to overrun the Saharunpore districts. On the 10th of February one of these columns was encountered by Colonel M'Causland from Nynce Tal, with the 66th Gorkhas, 200 cavalry, and 2 guns, near Buteree. The enemy lost 3 guns, and had 250 men killed. The British loss was 35 killed and wounded, including 2 officers wounded. The third rebel column, led by the Nawab of Najeebabad, crossed the river at Kunkhal, near Hurdwar, on the 10th of January, and were immediately attacked by Captain Boisragon with 100 Gorkhas, a few Sikhs, 10 Europeans, and 2 guns. The rebels fled in confusion on being charged by the Gorkhas in flanks, and by the Sikhs, led by Mr Melville of the civil service, in front; and the Moyapore dam being suddenly opened by Captain Drummond, of the canal department, as they were fording the stream on their retreat, great numbers of them were

drowned. The nawab himself was wounded, and his nephew fell by Captain Boisragon's own hand. Mutiny of 1857.

It is requisite here, in order to complete the view of operations at this time, to revert for a moment to the Bombay presidency, where the Bheels in the Ahmednugur and Khandesh collectorates, and adjoining districts, and along the Sautpoora Mountains, had risen in arms so early as September 1857. On the 8th of October a number of them, estimated at 1500 men, had posted themselves on a hill at Sinnore, 20 miles S. of Nassuk. Here they were on that day attacked by Lieutenant Henry, superintendent of the Ahmednugur police, who was killed, and his party repulsed with severe loss. On the 29th of the same month, Raghujee Bhangria, a Bheel chief, passed through the Ahmednugur districts, plundering and burning. During the end of November and December the Bheels, under Khajja Singh, in great force, lined the Sautpoora Hills, near the Sindhia Ghat, and are said to have carried off plunder from the adjacent villages to the amount of L.140,000. Towards the end of January the Bheels of Chandore were attacked by Captain Montgomery, superintendent of the Ahmednugur police, in a dense jungle, 12 miles S.E. of that place, with indifferent success. He gallantly led his men three times to the charge, but was himself badly wounded, and obliged to retire. Lieutenant Stuart of the nizam's infantry was killed; Lieutenant Davidson of the 19th native infantry, and Lieutenant Chamberlain of the 26th native infantry, wounded,—the former dangerously. On the 19th of February another engagement took place near the same spot, at Mahadeo Donger, when Captain Pottinger defeated the insurgent Bheels, and took many prisoners.

Returning to the operations in Oude, it is requisite, before describing the first advance of the commander-in-chief from Cawnpore, to give a brief summary of the movements of the Gorkha forces despatched by Jung Bahadur to the aid of the British, and subsequently supported by a powerful column under his own command. The Nepal chief had, soon after the outbreak, volunteered his assistance to the governor-general, but his overtures were at that time rejected. In July, however, 3000 Gorkhas had reached Goruckpore; but owing to the masses of rebels which surrounded them, they retreated from that place, with all the Europeans belonging to the station, on the 13th of August, towards Azimghur. At Gujhaba, 35 miles from Goruckpore, they were attacked by some thousands of rebels under Mohammed Hoossain, but soon repulsed their assailants, killing 150, and taking many prisoners, who, with two exceptions, were all put to death. The Gorkha loss was 2 killed and 7 wounded. Having arrived at Azimghur, which they found plundered by the rebels, they halted there, and on the 20th of September sent out 1000 men under Captain Boileau to attack a party of insurgents at Nundowlec, belonging to the Rajah of Attroniah. The Gorkhas were completely successful, and took three brass guns at the point of the bayonet, killing 100 of the enemy, and having themselves but 16 wounded. Jung Bahadur at this time sent a reinforcement of two regiments to the hill stations of Almora and Nynce Tal. Major Ramsay, with 150 Gorkhas, 25 irregular horse, and 30 gentlemen volunteers, before the above reinforcements arrived, attacked a body of 800 rebels advancing on Almora from Bareilly, and killed upwards of 100, losing only 1 risaldar killed, and 1 Gorkha wounded. On the 30th of October Colonel Wroughton, with 500 men of Her Majesty's 10th foot, 1100 Gorkhas, and some guns, drove a body of 5000 rebels, with 4 guns, from a position at Chanda. The Gorkhas gallantly captured the guns, and killed 400 of the enemy, losing 13 of their own men killed, and 60 wounded. The same Gorkhas had, on the 19th, defeated Hasan Yar Khan at Kudwa. In that action Messrs Jenkinson and Carnegie of the civil service greatly distinguished themselves, and killed 7 of the enemy.

Mutiny of
1857.

Mutiny of

The Gork-
ha allies.

Mutiny of
1857.

Towards the end of November the rebels from Lucknow pushed heavy columns to the south; so that the Gorkhas were compelled to again evacuate the Goruckpore district and Azimghur. On the 2d of December Jung Bahadur arrived at Segowlee, in the plains, having with him 9000 regular Gorkha troops and a multitude of irregulars.

On the 19th of December the *Calcutta Gazette* announced that Jung Bahadur was entering the plains of Hindustan to co-operate with the British troops in the restoration of order in the British provinces. Brigadier-General Macgregor was appointed to accompany the Nepalese chief; and a strong brigade under Colonel Franks was organized at Benares to co-operate with him by advancing in the direction of Jaunpore and Azimghur. Her Majesty's 97th and 20th foot, with a wing of the 10th regiment and some royal artillery, formed the nucleus of this force. On the 6th of January Jung Bahadur, with 14 regiments of infantry and 4 batteries of artillery of 6 guns each, took Goruckpore. The enemy's position was strong, but their resistance feeble. They lost 7 guns, and had 200 men killed; while the Gorkha loss was 2 killed and 7 wounded. Previous to this action a column of the Goruckpore rebels had been defeated at Sobanpore, 5 miles S.E. of Majhowlee, and 40 from Goruckpore, by Colonel Rowcroft with the naval brigade (about 160 men) and two Gorkha regiments. The rebels lost a gun, and had 200 killed; while there were but 4 wounded in Colonel Rowcroft's force. In the meantime the enemy had shown themselves in such force near Azimghur, that Colonel Longden, commanding there, had been compelled to retire. By the 22d of January Jung Bahadur's van had reached Belwa Bazar, on the Gogra, opposite Fyzabad; and Colonel Franks' column had been swelled by 4000 Gorkhas, some Madras troops, Sikhs, 200 sailors, while his artillery amounted to 24 guns. On the 4th of February the advanced troops of the Gorkha main army attacked and dispersed the rajah of Gondah's army near Fyzabad, with the loss to themselves of only 1 killed and 2 wounded. But Brigadier Franks was now rapidly pushing forward; and on the 19th of February he defeated at Chanda two armies of rebels, one of 8000 men, the other of 11,000. The loss of the enemy was very heavy. On the 23d the same officer gained a still more decided victory, killed 1800 of the rebels, and captured their standing camp and 20 guns. The British loss in the three actions was 2 killed and 16 wounded. Many rebel sepoys of the 13th, 15th, 20th, and 40th native infantry were killed in these engagements. Both the column of Brigadier Franks and that of Jung Bahadur joined the commander-in-chief at Lucknow without further serious opposition.

Capture of
Lucknow,
and close of
the revolt.

In the meantime, Sir J. Outram had repulsed incessant attacks on his post at Alumbagh, just on the outskirts of Lucknow, which he held with a fine division of 5000 men, composed of the 1st Madras fusiliers, the 5th fusiliers, the 75th, 78th, and 90th, with Brusier's Sikhs, Olphert's and Maude's batteries, some Madras sappers and miners, and the volunteer cavalry. To these regiments belongs the glory of maintaining the post of honour, and taking the lead in the final triumph at Lucknow. They were several times attacked at Alumbagh by immense masses of the enemy, and always repulsed them with terrible loss. On the 22d of December they took from the rebels 4 guns, an elephant, and great stores of ammunition. On the 12th and on the 16th of January they routed a mass of 30,000 men, which advanced on all sides of them. On February the 21st the rebels came out again in vast numbers, having sworn on the Koran to conquer or die. They formed in the shape of a crescent, and as the horns of their immense line began to converge on Alumbagh, General Outram attacked each extremity of it. They gave way almost at

Mutiny of
1857.

once, leaving 500 dead on the field; while the British had only 6 wounded. On the 25th they made another and a final effort, the begum and her son coming out on elephants to witness the conflict, which ended still more disastrously for them than the preceding. These successes were a presage of the easy reduction of the city, which fell on the 19th of March. Sir C. Campbell had been detained at Cawnpore longer than was expected by the non-arrival of the siege train from Agra. At last, on the 10th of February, an extra bridge having been thrown over the Ganges from the Cawnpore side, the passage began. Such, however, was the prodigious number of men and animals, that it was many days ere they had crossed. The whole road from Cawnpore to Alumbagh was lined with troops and baggage-cattle, among which were 16,000 camels. The actual numbers of Sir C. Campbell's main army were—infantry, 11,442; cavalry, 3961; artillery, 1669; naval brigade, 331; sappers and miners, 1970;—grand total, 19,373. Thus, with Outram's and Franks' divisions of 5000 men each, and Jung Bahadur's army of 10,000 Gorkhas, the whole force arrayed against Lucknow fell little short of 40,000 men, with 180 guns; and it may justly be said that an array so formidable and so well appointed never was seen in Hindustan.

On the 6th of March, Sir C. Campbell having arrived a few days previously, General Outram, with 5000 men and 30 guns, crossed the Goomtee, and took post to the E. of the city, pushing his reconnoissances to the S., and after repulsing an attack, bivouacked on the field of Chinhutt, where Sir H. Lawrence was so disastrously defeated. On the 7th Sir J. Outram despatched General Hope Grant with 2000 cavalry to the N.E., to make a reconnoissance, and during his absence the enemy made a second and more serious attack. On the 9th Sir James turned the enemy's first line of works, which, though constructed with great care and skill by the revolted sappers and miners from Roorkee, were by a grave mistake made without protections from a flanking fire. In consequence, Outram's guns enfiladed the whole line, and enabled General Lugard's division, on the 10th, to carry the Martiniere and adjacent works on the S. of the city; and shortly after, the whole left of the enemy's earthworks, to within 800 yards of Banks' house. On the 10th this latter post was taken, and on the 11th the same division carried the begum's palace, which had been fortified in a way to make it defensible against a whole army. Here 600 bodies of sepoys of the 22d, 38th, and other regiments, were counted; and General Lugard lost about 100 men of his division in killed and wounded; among them Captain Hodson, the capturer of the King of Delhi, and well-known commander of irregular horse. On the same day Jung Bahadur joined with his Gorkhas. A severe struggle now took place in the direction of the Moosa Bagh, to the N.W. of the city; and here Captain Cooper of the engineers, Captain Moorsom of Sir J. Outram's staff, and many other gallant men, fell. On the 13th Sir Colin took the Imambara, and opened a tremendous fire on the Kaiser Bagh, the walls of which were shivered to pieces. On the 14th General Outram carried the town between the iron bridge and the Residency; and thousands of the enemy began now to stream out of the city, taking the road to Rohilcund. On the 16th the Muchee Bhawan and Great Imambara were captured; and on the 18th the Gorkhas carried a very strong position in front of Alumbagh. A detachment of these troops brought in Mrs Orr and Miss Madeline Jackson, who had been prisoners in the hands of the rebels since the advance of General Havelock. On the 19th the whole city was in possession of the British; and though many thousands of the rebels escaped, and a desultory warfare ensued, the close of the great revolt may be dated from this epoch.

NORTH-WEST TERRITORY. See HUDSON'S BAY TERRITORY.

NORTHWICH, a market-town of England, in the county of Chester, on the left bank of the Weaver, near its confluence with the Dane, 15 miles N.E. of Chester, and 155 N.W. of London. It has an old-fashioned appearance, and contains many ancient buildings. The church, which is large, is remarkable for its semicircular chancel and curiously carved roof. There are also places of worship for Independents, Baptists, Wesleyan and Primitive Methodists, and several schools. Northwich is chiefly important for its salt mines and brine springs, the former of

which have been worked since the seventeenth century, and are believed to be the richest salt mines in the world. The brine springs, however, are now more extensively used, and are calculated to yield from 300,000 to 400,000 tons of salt annually. This forms the principal article of trade in Northwich, being conveyed to Liverpool by the Weaver and Mersey, on which about 300 vessels are employed in this business. Ship-building, brick-making, iron and brass founding, brewing, and other avocations, are carried on here; and fairs are held three times a year. Pop. (1851) 1377.

N O R W A Y.

History.

NORWAY is an extensive country in the north of Europe, united with Sweden under one king. All the territory which is now comprised by Norway and Sweden, was designated *Scandia* by the ancients. Pliny calls it *Scandia insula*, an appellation which derives its origin from the circumstance of the Romans, in the time of their great naturalist, being only acquainted with that part of the country called Skanen or Skonen, the little information which they possessed being obtained from some Germans. This is the ancient province of Schonen or Scania, the most southerly of Sweden. The name was afterwards changed to Scandinavia, which has been called the "store-house of nations," but without any just title to such a distinction. It seems now quite certain that Scandinavia was not the native country of the Scythians or Goths, but that they migrated from Asia to Europe. The fact of Pliny having designated Scandinavia as an island of considerable although uncertain magnitude, has also given rise to some discussion. To the imperfect knowledge of geography which the ancients possessed may reasonably be attributed their mistaken notion as to the insular position of these countries.

Origin of
the name.

But our present purpose is with Norway, which in Swedish is called *Norrige*, and in Danish, *Norge* (pronounced *Norre*). "In spite of the vague ideas which the ancients entertained of the northern countries of Europe," says Malte-Brun, "it cannot be doubted that the country which Pliny calls Nerigon is Norway. Many geographers¹ have asserted that the name signifies the "Way of the North;"² but its true etymology seems to be *Nor-Rige*, "Kingdom of the North," or rather, perhaps, assuming the word *Nor* as signifying *gulf*, "Kingdom of Gulfs," because in effect its coasts are much more indented than those of Sweden. We thus see that the name of Nerigon has much more analogy with that of *Norrige* than with that of *Norweg*, which at the first glance appears to be the origin of the modern name. The early history of Norway is interwoven with the annals of Sweden and Denmark, and consists in legends contained in the *Heimskringla* or *Saga*, a collection of ancient manuscripts, which is to Norway what the *Edda* is to Iceland. The petty sovereigns who held sway in Norway in remote ages were independent, but appear to have acknowledged a kind of supremacy in the kings of Sweden and Denmark, probably more nominal than real; but until the ninth or tenth century little is known of the annals of the country. The Norwegians, of course, constituted no inconsiderable proportion of those daring adventurers who, under the general name of Normans on the Continent, and Danes in Britain, became at one time the terror of all the maritime parts of Europe.³

The Royal Northern Antiquarian Society of Copenhagen has published a series of the *Saga*, comprehending the his-

torical account of events which belong to European history, History, as well as to that of Scandinavia, during the eleventh and twelfth centuries. It includes a period of about 170 years, beginning with the *Saga* of St Olaf, the contemporary of Canute the Great of England, who assumed the crown of Norway in 1013, and continuing the series until the death of Magnus Erlingsson in a sea-fight with Sverrer I. in 1184. This is one of the most curious and minute pictures of an age long past which the literature of Europe is possessed of. It is not only valuable as an historical document, confirming or adding to our stock of facts relative to a dark period of English history, but as a record of the social condition of the country at that time, and of the influence of the Thing, or assembly of the people; a reference of all matters to this popular convocation being one of the most striking facts recorded in the *Saga*. From these rude annals we learn that, at a period immediately preceding the first traces of free institutions in our own country, similar institutions existed in great activity amongst these northern people. It seems a fair inference from these facts, therefore, that we owe the political institutions which we enjoy to the Danes and Normans, who were more likely to impose their own peculiar institutions upon those whom they subdued, than to receive institutions from the conquered.

From other *Sagas* preceding that of St Olaf, we learn, that about the middle of the ninth century Halfden the Black divided Norway into five districts, with fixed head places for holding Things in each. At these assemblies laws were framed suitable to the local circumstances of each district, which gave its name to the code. This potentate was succeeded by the celebrated Harold Harfagr, or the Fair-Haired, who ascended the throne at ten years of age, and reigned from 863 to 936. This warlike monarch, after long fighting, reduced all the independent nobles or petty kings to the condition of subjects, and consolidated the various principalities of Norway into one kingdom. Thus was consummated in a single reign, and that, too, in the ninth century, a work which afterwards cost the other nations of Europe several centuries of bloodshed and contention. But this was more easily accomplished in Norway than elsewhere; for in that country the great nobility never had feudal powers, and consequently those who were under them as servants were bound by no such ties of vassalage as the retainers of a Highland chieftain or a Norman baron. They were not taught passive and unconditional submission to a superior, although he might bear the title of king; for before a small sovereign could make war he was under the necessity of assembling the Thing, and obtaining its sanction. The equal division of property among children, which extended to the crown itself, prevented the accumulation of power in the hands of individuals; and the circum-

Norway. stance of the total want of fortresses, castles, or strongholds in the country, owing to the division of estates, effectually prevented a nobility from attaining the same power with the nobles of feudal countries, and setting the royal authority at defiance. Some of these nobility or small kings colonized Iceland; and Normandy was conquered by Rolf Gangr, one of those whom Harold Harfagr expelled from Norway. In this king's reign Christianity was introduced into the country, and from this period the events recorded in the historical Saga may claim some degree of confidence.¹ The length of this reign was no doubt favourable to the lower orders, by consolidating their institutions, which, as they weakened the authority of the petty kings, were favoured by Harold. Eric, his son and successor, whom he had associated with himself in the royal authority, was deposed by the Thing on account of his cruelty, and a younger brother succeeded him. Hakon, which was the name of this son of Harfagr, was brought up from his childhood at the court of Athelstane, King of England. He reigned nineteen years, during which period there was frequent reference to the Things, both for amending the laws and for the dissemination of Christianity. It appears that, in attempting to establish the religion of the Cross in his dominions, Hakon had recourse to what were considered as unconstitutional means; for we find that, at a meeting of the Thing, held in the year 956, a husbandman named Asbiorn, of Medalhuus, stood up and declared, on the part of his neighbours and of himself, "that they had elected Hakon to be their king upon the condition that freedom of religion and freedom of conscience should be warranted to every man; and if the king persisted in attempting to suppress their ancient faith, they would elect another king;" adding, "and now, king, make thy choice." This is certainly one of the most striking instances of parliamentary patriotism to be met with in the history of Europe; and we must descend six or seven centuries nearer to the present time before we can match it in the annals of our own country. Hakon was not only compelled to give way, but also to take part in the heathen ceremonies of the meeting. This king was slain in 963, in a battle with the sons of his elder brother Eric, upon whom Athelstane of England had conferred the kingdom of Northumberland.

It appears that, after the death of Harfagr, the small kings again had risen to some degree of power, and that each in his own assembly, called also a Thing, had exercised a limited authority. Olaf the Saint, before he assumed the name of king, consulted one of these assemblies of the nobility as to the way of proposing his claim as heir of Harfagr to the general Things of the people; and he proceeded in such a manner as to show that their voice alone was insufficient to constitute him supreme chief in the land, without the sanction of the general Thing. These institutions appear to have always conferred or confirmed the royal prerogative, and to have been of great importance in that age amongst the whole Scandinavian people. In cases where the good of the community was at stake, they set the royal authority at defiance, and obliged the sovereign to accept of such international contracts as the Things of both countries conceived was for their mutual benefit. The Thing of Sweden compelled the sovereign of that country to conclude a peace with Norway, and to bestow his daughter in marriage on King Olaf, towards whom he cherished implacable enmity. Olaf had the title of Saint conferred on

him for the exertions which he made to introduce Christianity amongst his subjects; but in prosecution of this object he exercised the most atrocious cruelties, and completely alienated the affections of his people. He attempted to govern without the intervention of the Things, which became the cause of his ruin; for when Canute the Great, who conquered Norway, invaded his dominions, the people literally "stopped the supplies;" and, unable to collect a force sufficient to oppose the King of England, he was compelled to seek refuge in Russia. For the purpose of recovering his crown, he landed in Sweden with a few followers, and, having received an accession to his force from the king of that country, who was his brother-in-law, marched from the Gulf of Finland across the peninsula to the Fjord or Gulf of Trondhjem. In the meantime the Thing of Norway raised an army of 12,000 bonder, and placed it under the command of Olver of Egge. At the debouche of the valley of Værdal they met Olaf at the head of about 4000 adventurers. The conflict could not be doubtful where there was such an inequality of numbers, and where the superiority lay on the side of those who were fighting in defence of their liberties. King Olaf was defeated and slain, without even showing the prudence and courage which had distinguished his early career. This battle was fought on the 31st of August 1030, and not on the 29th of June or July 1033, as is commonly stated.² The body of the fallen monarch was transported to St Clement's church in Trondhjem, which had been erected by himself. In return for the services which he had rendered the church, the clergy soon afterwards canonized him; and even at Constantinople temples were erected to his memory. His tomb was regarded as a consecrated spot, to which pilgrimages were performed, not only by ardent devotees from the north, but also from the south of Europe.

Canute the Great did not long remain in Norway; and from the period of Olaf's death the country was ruled by native monarchs, who even for a time governed Denmark. It may be gathered from the ancient chronicles before referred to, that at this period society was composed of four distinct orders. The first was the nobility, who were descendants of royal families; and, without regard to priority of birth, those who were descended both on the mother's side and father's side from Harfagr were eligible to the supreme monarchy. They appear to have had no civil power or privilege as nobles, but merely this *odelsbaarn-ret* to the crown. The *odelsbaarnmen*, *bondemen*, or husbandmen, were the proprietors of lands held neither from the king nor from any feudal superior. These were the people who had a voice at the Things. A third order consisted of the unfree men, holding land for services as vassals or as labourers in cottages, but who had no voice in the Things in respect of their land. A fourth order was composed of the *trælle* or domestic slaves, who were private property, and in a lower state than the former class. This condition of society, which was equivalent to slavery, was abolished by Magnus VII., who reigned from 1319 to 1344.

The most important event in the history of Norway, Sweden, and Denmark, in the middle ages, was the union of the three kingdoms under one sovereign, Margaret, daughter of Waldemar, King of Denmark, which was effected by the league of Calmar, in the year 1397. The circumstances which led to this remarkable occurrence will

¹ Harold Harfagr was born in the year 853; he began to reign in 863, and died in 936. St Olaf's father was Harold Grændske, his grandfather Gudrod, his great-grandfather Biorn Stærke, and his great-great-grandfather Harold Harfagr; and St Olaf was born A.D. 995, only fifty-nine years after the death of his great progenitor Harfagr. A contemporary of St Olaf was therefore a credible source of information for all the events of Harfagr's reign, such as the conquest of Normandy by Rolf Gangr, the colonization of Iceland, &c. (Laing's *Journal of a Residence in Norway*.)

² This is put beyond a doubt by a circumstance which all accounts of the battle mention, namely, that a total eclipse of the sun occurred on the same day. Professor Hansteen of Christiania has calculated that such a celestial phenomenon could only have taken place on the 31st of August 1030.

Norway. be found narrated in the article DENMARK. Had this princess been as capable of conquering national prejudices as she was of defeating armies, her dominions would have constituted a great and powerful monarchy. But the passions of her people were more than a match for her policy; and it was no doubt better that the three nations which she governed should each remain in quiet possession of its own freedom, as enjoyed under its own form of government and laws, than that they should lay aside all differences, and, heartily uniting as one kingdom and people, become the terror and scourge of Southern Europe. Margaret died without issue; but during her lifetime she appointed her grand-nephew, whom some historians call her cousin, Eric, a descendant of the dukes of Pomerania, as her successor; and he succeeded to the triple crown of Scandinavia in 1412. The union, however, was far from being cordial; and for rather more than a century local insurrections from time to time broke out and distracted the country. The Swedes, in particular, felt great reluctance to submit to a foreign dynasty; and after various attempts on their part to shake themselves free from the compact of Calmar, the oppression and cruelty of Christian II. led to the final separation of Sweden in 1520, under the celebrated Gustavus Erickson or Vasa. Norway and Denmark, however, remained under one sceptre, till, at the adjustment of European affairs after the fall of Napoleon, Norway was separated from Denmark, and united to the crown of Sweden. This took place in the year 1814.

The circumstances which led to the forcible separation of two countries that had for centuries been united by the closest relations, and the union of one of them with another country which had for as many ages been regarded as a natural enemy, may be shortly stated. The grand object of the leading powers was to induce every state to join in the league against Napoleon; and Sweden, in consideration of an ample bribe, acceded to the general confederacy. One of the foulest stains on the escutcheon of Great Britain is the treaty which she entered into with Sweden, dated 3d March 1813. By this notorious compact against the liberties of a whole people, England gave to the King of Sweden the kingdom of Norway (which was no more hers than Rome or Peking), together with Guadaloupe, and a million of pounds sterling, as a remuneration to his Swedish Majesty for joining the allied powers against France.¹ After the battle of Leipsic, fought in October 1813, the Crown Prince of Sweden entered Denmark with his army; and after some bloody scenes in Holstein, peace was concluded at Kiel on the 14th of January 1814. By this treaty Denmark gave up all right to Norway, considering it as quite hopeless to enter into a contest with Sweden and England. Although the King of Denmark might relinquish his claim to the sovereignty of Norway, this was no reason for the people of that country making an unconditional surrender of themselves to a foreign potentate. They declared themselves an independent nation, framed a constitution of their own, and proclaimed Prince Christian, son of their former sovereign, and governor of Norway, as their lawful king. Not a little blood was shed in the contention between Sweden and Norway; and England actively interfered by blockading the ports of Norway, for the purpose of starving the inhabitants of the country into subjection. But a speedy settlement of the question became necessary to all parties. The constitution which the Norwegians had prepared in April 1814, and which

they were in arms to maintain, was guaranteed to them, upon condition of their accepting along with it the Swedish monarch as king, and the Crown Prince of Denmark abdicating the throne. Matters were arranged on this footing; and on the 17th May 1814, both parties, the King of Sweden and the Norwegian nation, solemnly entered into a compact to the effect stated, under the sanction and guarantee of the allied powers, and of Great Britain amongst the rest.² By the treaty the entire independence of Norway as a kingdom was secured, the crowns alone being united, as in the case of Hanover and England. She had a constitution of her own framing, a legislature of her own electing, without being interfered with by any foreign authority in the exercise of her right, and laws of her own making and administering; in short, Norway remained a pure democracy in all but the name.

Since this union of Norway and Sweden under one sovereign, there have occurred only two events of any importance in the history of the former. The first was the abolition of hereditary nobility by the Storting; and the second was an attempt of the Swedish cabinet in 1824 to force on the Norwegian people an entire amalgamation of their country with Sweden. But the firmness of the Storting or Parliament, the honourable feelings of the sovereign, and, it is said, the interference of Russia on the part of the allied powers, prevented such an infamous attempt to violate the faith of treaties, and bring disgrace upon those who had guaranteed them. Great Britain, as a party to the treaty of 1813, and as having inflicted some injury on the country by her ships of war, was especially bound to protect the liberties and national independence of Norway, and to preserve her from becoming a mere province of Sweden, as Poland is now of Russia.

The facts relative to the abolition of hereditary nobility may be shortly stated. It is fixed that the executive power has not a final veto, but only a suspensive negative, till the law is passed by three successive Storthings. In the year 1815 both chambers of the Storting proposed and passed a motion to abolish nobility for ever in Norway. The slender remains of this class were of foreign, and almost in every instance of recent origin; besides, few of them had enough of property to enable them to hold a dignified station in society. By the law of succession land is equally divided amongst all the children, so that large estates could not be entailed on the possessor of the family title; and hence, to maintain his rank and respectability, a nobleman must have become a placeman or a pensioner, or engaged in operations which would bring nobility into contempt. The existence of a hereditary nobility in a country where the law of primogeniture was unknown in the succession to real property, seemed therefore an anomaly, which, in any circumstances, could not long be tolerated, and which was altogether unsuitable to the state of things which had long obtained in Norway. The royal assent, however, was refused to the proposed enactment in 1815, and again in the year 1818, after it had passed through a second Storting. To prevent it from passing a third time became the grand object of government; for then it would necessarily have become the law of the land, with or without the royal consent. In 1821, the year when the measure was to be again brought forward, the king in person repaired to Christiania, and used every means to induce the Storting to abandon it; but in vain. Six thousand soldiers were marched to the neighbourhood of that city, to overawe both the legis-

¹ In the article containing the accession of England to the treaty, after various mutual stipulations, there is a provision containing the following words:—"And his majesty the King of Sweden engages that this union shall take place with every possible regard and consideration for the happiness and liberty of the people of Norway."

² It is a fact worthy of being recorded, that the committee which drew up this constitution, and laid it before the National Assembly, sat only four days, viz., from the 12th to the 16th of April. That so perfect a model of a free constitution should have been framed in so short a period is truly marvellous; especially as it was not a rough, unfinished outline, but a system of government complete in all its details.

Norway. lature and the people; and extreme irritation prevailed. At this critical moment, when the flames of civil war were about to be kindled, both the Russian and American ministers interfered. What arguments or remonstrances they employed are unknown; but the fact is, that government lowered its tone, the troops were withdrawn, and the Swedish government gave way. The Storthing having passed the measure abolishing hereditary nobility for the third time, it consequently became law. Norway therefore remains a pure democracy, federally united with the monarchy of Sweden. Its constitution has outlived two dangerous attacks upon it; and as the principles upon which it is based have been developed by practice, it has gained additional strength, and been further secured by the love and veneration of the people. The sudden disjunction of Denmark and Norway left, of course, much business to be adjusted between individuals of the two countries. It thus occasioned much distress and loss to persons having connections and property in both; and it still produces a constant intercourse. Few, we believe, will admire the manner in which the union between Sweden and Norway was effected; but as few will doubt the benefits which must result to both from the exchange of mutual hostility for mutual cordiality, and to a certain extent an identity of interests.

Physical aspect.

If the reader turn to the map of Europe, he will find that Norway extends from the 58th to the 71st degree of N. Lat., and at the broadest from the 5th to about the 31st degree of E. Long. On the E. it is bounded by Sweden and Russian Lapland, W. by the North Sea, S. by the Skagerrack, and N. by the Arctic Ocean. At the broadest part it is scarcely 300 miles across, and N. of the 63d degree of latitude the breadth is very inconsiderable, the country narrowing to a mere belt. Its shape is peculiar, and, in the main, it resembles that of a Florence flask,—the rounded bottom being presented to the south, and the long narrow neck stretching to the north. Norway thus begins about the parallel where Scotland ends. The most southerly headland in the former, that is the Naes, is nearly in the same parallel as the Pentland Frith, which divides the latter country from the Orkney Islands. The sea-coast presents many features similar to those which characterize Iceland, the north of Scotland, Newfoundland, Nova Scotia, and other islands and continental tracts of country exposed to the storms, the currents, and the perpetual buffetings of the Northern Ocean. The action of the sea alone, however, could not have formed such immense fissures as are found in the solid primary rock on the Norwegian coast. The theory of the elevation of the land by volcanic impulse from below seems alone sufficient to account for such phenomena.¹

The greater part of Norway may be said to have an outer and an inner coast, the former being a succession of rocky islands of all dimensions, from a mere point to more than a mile in length, and lying within about a mile of the mainland, thus circling all the coast as with a girdle. Boats and small vessels make their coasting voyages within the rocks; for, even when the ocean is strongly agitated, the outer barrier acts as a sort of breakwater, preventing the channel within from being thrown into violent commotion, except where directly open to the sea, when the wind rushes in with great force and agitates the waves.

Fjords.

Those immense arms of the sea which penetrate deep into the country are called *fjords* in Norway; a name in geographical nomenclature identifying them with the

firths of Scotland, to which they bear a slight resemblance, and also to the maritime lochs so numerous on the west coast of that country; but the nearest approach to similarity, although it falls far short, is an inlet of the sea on the west coast of Ireland known as the Killeries. To enumerate these fjords were only to present a catalogue of names designating the same object in different situations and of different sizes. They vary from 60 to 200 miles in length, and from being several miles to less than a gunshot in breadth; and altogether they constitute one of the most remarkable physical features of the country. In many of these fjords the rocks rise precipitously on either side, and the water is of great depth. The inland streams generally empty themselves into the fjords; and, as in the case of the firths of Forth, Clyde, and others, in Scotland, it is often difficult to say where the river ends and the ocean begins. All along the rock-bound coast these arms of the sea succeed each other with much regularity. In penetrating within their sombre and sometimes dangerous mouths, the scene is all at once changed, presenting at the bottom of these bays, creeks, and other indentations, towns of a pleasant and cheerful aspect, and banks finely wooded with all the varieties of those forest trees which we are accustomed to meet in more temperate latitudes,—such as oak, ash, elder, and elm trees,—and studded with cottages, farmhouses, and country residences, indicating taste and comfort, if not luxury and wealth. The tide rushes into many of those fjords with great violence, especially on the north-westerly quarter of the peninsula. This is readily accounted for from the fact, that the interior basins are often very capacious, whilst the mouths by which the water flows in to fill them are frequently very confined. Opposite to Folden Fiord is the Maelström, or Moskoestrom, long celebrated as the most appalling whirlpool in Europe; but it owes much of its reputation to the exaggerated accounts of travellers. It is situated nearly at the extremity of the range of the Lofoden Islands, beginning between Moskoenæs and Moskoe, and exhausting itself between Varoe and Rost, the last of which is the most westerly of the Lofodens. The whirlpool is simply caused by the rushing of the ocean, as the tide rises and falls, between this chain of islands, which impedes its course like the narrow mouths of the fjords. The relative position of the surrounding islands causes the Maelström to form a large circle; and the great inequalities of its bottom, which, from a few fathoms, deepens suddenly in many parts to 200, increase the violence of the current. A coast like that of Norway, so beset with irregular currents, islands, and rocks, many of the latter close under water, requires at all times to be approached with extreme care, but particularly so in westerly gales, when it becomes a lee-shore. The Norwegian government has recently completed a series of splendid charts, on a scale of 3 inches to the mile (with necessary sailing directions), of the whole coast, from the Christiania Fiord, round the North Cape, to the Russian frontier in the White Sea; a most important and valuable addition to hydrography, of which the lamented Sir Francis Beaufort, our hydrographer of the navy, did not fail to avail himself, and caused fifteen large sheets, together with an index chart, to be published therefrom in 1855, for the benefit of British mariners. Neither are there wanting admirable maps of the interior, prepared by Professor Munch, by Capt. Rosen of the Engineers, and by Capt. Waligorski and Hergoland.

Norway.

The interior of Norway is almost one immense mass of Mountains, rocky mountains and plateaux. It is mountainous, but it is

¹ Indeed, the large rounded boulder-stones found on the tops of the highest mountains afford evidence sufficient of the fact that at one time Norway had been submerged beneath the Northern Ocean. That the sea never flowed in this quarter of the globe (and consequently in every other), eight thousand feet (the height of the highest mountains) above its present level, may readily be taken for granted. We may, therefore, conclude, that the land has been raised by some mighty power; and we know of none which could effect this but the pent-up fire and compressed gases of a volcano, which, striving for vent, upheaved the solid pavement of the globe which lay above them, and thus broke it up into innumerable fragments.

Norway.

so rather by reason of its general elevation than from the conspicuous altitude of its summits. The mountains do not form continuous chains or ridges; neither are they a series of detached elevations; but, especially in the S., they form plateaux or table-lands of great breadth, and generally more or less connected together, though occasionally separated by deep but always narrow valleys. These table-lands are the fjelds of Norway, and are usually distinguished by specific names, as the Dovre Fjeld, Sogne Fjeld, Stagen Fjeld, &c. Their summits are often so level that, did roads exist, a coach and four might be driven along and across them for many miles. The surface of the country may be distinguished into two distinct portions—the comparatively narrow district extending from near Trondhjem to the North Cape, a distance of more than 600 miles, and the more expanded portion, 400 miles in length, from Trondhjem to the Naes of Norway. Throughout the former portion the mountains cling, as it were, to the coast; and though Norway here occupies only one-fourth of the breadth of the peninsula, it contains all the more considerable elevations. They assume here more the form of a connected range than in the southern part of the country, and are known by the name of the Kjölen Mountains. The highest land is the mass called Sulitelma, some of the summits of which rise to the height of more than 6000 feet above the level of the sea. South of Trondhjem (in Lat. 63. N.) the high ground occupies by far the greatest part of the breadth of Norway, and on the parallel of the Dovre Fjeld, fully half the breadth of the peninsula. “By a rude estimation,” says Professor Forbes, “on Professor Keilhau’s map, I find that the portion of the surface of Norway, S. of the Trondhjem Fiord, which exceeds 3000 feet above the sea, amounts to very nearly 40 per cent. of the whole; and when it is recollected that only one summit exceeds 8000, and that the spaces exceeding 6000 are almost inappreciable on the map, it will be more clearly understood how completely the mountains have the character of table-lands, whose average height probably rather falls short of than exceeds 4000 feet.” (Forbes.) The Dovre Fjeld, lying between 62. and 63. of N. Lat., is a table-land of an average height of rather more than 3000 feet above the sea, and having mountains rising, in the case of Sneehøette, and possibly one or two others, to the height of above 7000 feet. Ymes-Fjeld, the highest summit in Norway, in Lat. 61. 30. N., is estimated at 8400 feet above the level of the sea.

Travellers are proverbially prone to give exaggerated descriptions of the physical features of the countries which they traverse; and from this cause our ideas of the height of some of the Norwegian mountains, and the sublimity of the scenery which they present, have occasionally been pitched rather above the truth, which is the case with respect to the Dovre Fjeld. Mr Laing, in his excellent account of the country, thus describes this great natural feature of Norway:—“The Dovre Fjeld here (at Jerkin, on the northern verge of the range) may be from 24 to 28 miles across. When we give things their real names we take away much of their imagined grandeur. The Dovre Fjeld sounds well, and we fancy it a vast and sublime natural feature. It really is no more than a *fell*, like those of Yorkshire or Cumberland; an elevated tract of ground, whence run waters in opposite directions, and which forms the base of a number of detached hills of moderate elevation. In fact, as a scene impressing the traveller with ideas of vast and lonely grandeur, the tract from the waters of the Tay to those of the Spey, by Dalnacardoch, Dalwhinny, and Pitmain, greatly surpasses it. You are indeed 3000 feet above the level of the sea; but that is not seen; it is a matter of reflection and information. You look down upon nothing below you, and look up only

to hills of moderate elevation. Sneehøette alone comes up to a mountain magnitude: it is 7300 feet above the sea; but this fell is 3000 feet at this farm-house (at Jerkin), which is about 12 miles from the base of Sneehøette. The actual height, therefore, of this mountain, for the eye, is about the same as that of Ben Nevis, about 4300 feet, with the disadvantage of gaining its apparent height by a slow rise from the fell. There is a considerable mass of snow in a hollow on the bosom of Sneehøette, but not more than remains for great part of the summer on hills in Aberdeenshire,—nothing like a glacier. The head and shoulder are clear of snow. The most extraordinary feature of this mountain tract is, that the surface of the fell, and of Sneehøette to its summit, is covered with, or, more properly, is composed of, rounded masses of gneiss and granite, from the size of a man’s head to that of the hull of a ship. These loose rolled masses are covered with soil in some places; in others they are bare, just as they were left by the torrent which must have rounded them and deposited them in this region.”¹

Norway

The glaciers of Norway are neither so numerous nor so remarkable, either in beauty or extent, as those in Alpine countries. The Norwegian mountains are, for the most part, continuous table-topped rocks, of an average height of from about 3000 to 6000 feet, intersected with deep fissures, forming the valleys, lakes, rivers, and fiords at their base. On the highest summit of these table-topped mountains the snow lodges, the point of perpetual congelation being between 4000 and 5000 feet above the sea-level. It lies very deep, and in some cases extends in almost one uniform mass for many miles. The largest of these snow-fields is that of Justedalsbraen (sometimes called Sneebraen), and Folgefonden; the latter an extensive plateau of some 30 miles long, by 6 to 18 miles in breadth. Professor Wittich, who ascended the Folgefonden, says, that at most places the snow-field extends to the steep precipices with which the mountainous mass on which it rests terminates on all sides; and that in those places where its edges could be observed, the snow had a thickness of about 40 feet.

Glaciers.

Thanks to Professor Forbes, who visited Norway in 1851, we have now been made acquainted with the physical geography of that country, in connection with the snow-fields and glaciers, of which little or nothing was previously known. He describes the Nygaard Glacier, on the Justedalsbraen, as in all probability the most regularly developed glacier in Norway. Like the glaciers of Bondhuus and the Sphelle Glacier, it sweeps down into the very midst of the verdure of the valley. Professor Forbes’s observations extended also along the entire coast, up which he proceeded in one of the Norwegian steamboats which every summer thread their way to the North Cape through the numerous islands which lie off the land. The glaciers are not so numerous as might be expected to the northwards, but in some cases they descend very close to the sea, as in the case of those of the Nus Fiord, “the northernmost glaciers on the continent of Europe which descend below the snow-line.”

There are a number of lakes in Norway, the largest of which is the Myosen (now traversed by a steam-vessel), a splendid sheet of water, about 60 miles in length, and from 1 to 10 in breadth. Its scenery has been classed with the pastoral or beautiful, rather than with the sublime. Its shores are well cultivated; and with the exception of a few rough promontories dipping into the lake, the slopes are easy, and yield fine crops of oats, bere, flax, pease, and potatoes. Its direction, like that of a great many of the lakes and rivers in Norway, is from N.W. to S.E., crossing the 61st parallel of N. Lat. The depth of the Myosen varies greatly, but it is considered shallower than most of

¹ Laing’s *Residence in Norway*, p. 52–3.

Norway. the other Norwegian lakes. The depth in the lower parts is not more than 40 fathoms; often it is much less; but in the upper part it has been found to exceed a hundred. Yet even this is nothing in comparison with the depth of the other lakes, particularly of the Fahmund Soe, which is reputed to be unfathomable; a distinction always allotted to the deepest lake in every mountainous country. A large stream, called the Vormen Elv, issues from the southern limit of Lake Myosen; and at Lillehammer, which is its northern extremity, it forms a communication with Lake Losna by the River Lougen. Into this lake flows a river which rises in the Dovre Fjeld range of mountains, and appears to be the one alluded to by Mr Laing in the following passage:—"The stream which runs through Gulbrandsdal and the Myosen, and reaches the sea at Frederickstad, being the same I left at Lien, comes down from the hills at or near Lessoe, and is there divided into two branches, one of which, as above stated, runs into the Myosen, and the other into the North Sea at the fiord in Romsdal amt, in which the town of Molde is situated; thus including in its delta between four and five degrees of latitude, and all the west and south of Norway. The course of this little river from Lessoe to the sea is very important, as it gives precision to our ideas of the shape and direction of the Dovre Fjeld, and its connection with the Hurunger, the Fille, and the Hardanger Mountains." This river must therefore have a course of probably 100 miles in a north-westerly, and above 250 in a south-easterly direction. It is in several parts of its course of considerable breadth, and at more than 100 miles from its embouchure is described as a large, dark-coloured, and rapid river. A still larger stream is the Glommen, called by way of distinction Stor Elven, or the Great River, from its being the largest in Norway. It rises in the government of Trondhjem, not far from Oresund Lake, through which it runs; and it afterwards traverses the extensive government of Christiania, flowing through Osterdaelen and Hedemarken, passing Kongsvinger, and finally falling into the sea at Frederickstad, after a course, reckoning its sinuosities, of probably more than 400 miles, all in Norway. From the heart of this continent it opens an easy communication with the ocean, and through its means the produce of the interior is brought down to the coast. At about 200 miles from the sea it is described as a fine majestic stream, 200 yards in breadth. Navigation, however, is obstructed by numerous falls, one of which, not far from its mouth, is called the cataract of Sarpen, the roar of which is heard at a great distance. There are other falls on the same river; but the most stupendous natural phenomenon of this description is situated upon the opposite side of the mountain range, on streams which flow into the North Sea. Mr Lloyd¹ (and all subsequent travellers agree with him) describes the falls of Rjukanfos and Voringfos as particularly grand, the first having a perpendicular descent of 450 feet, and the second of 900 feet, the body of water in both cases being very considerable. Mr Forsell, in giving some statistical information regarding Norway, mentions other falls even more stupendous than these. The waterfalls of Norway are, in fact, extremely numerous, and some of them are grand beyond description. "Running water of a bright and sparkling green is seen on every side, at least in the valleys; it pours over cliffs often in a single leap, but more frequently and more effectively in a series of broken falls, spreading laterally as it descends, and riveting the imagination for a long time together in the attempt to trace its subtle ramifications. The sound is rather a murmur than a roar, so divided are the streams, and so numerous the shelves of rock tipped with foam; whilst a luxuriant vegetation of birch and alder overarches

Norway. the whole, instead of being repelled by the wild tempest of air which accompanies the greater cataract. At other times single threads of snow-white water stretch down a steep of 2000 feet or more, connecting the Fjelde above and the valley below; they look so slender that we wonder at their absolute uniformity and perfect whiteness throughout so great a space, never dissipated in air, never disappearing under *débris*; but on approaching these seeming threads we are astonished at their volume, which is usually such as completely to stop communication from bank to bank." (Forbes.) There are many other lakes and rivers in Norway besides those which we have described, amongst which we may mention the Torris Elv, called the Odderen Elv during part of its upper course, a large stream, which enters the sea at Christiansand; the Topdals, which falls into the sea near the same place; the Louven Elv, which rises in the Hardanger Fjelde, traverses several long, narrow lakes, passes through Königsberg, and enters the sea near Nauvig, in Lat. 59.; and between this stream and the Lougen, which lies considerably to the N.E., there is more than one large river. A multitude of streams also run into the North Sea. The most important of these is the Namsen (now the favourite resort of our countrymen for salmon-fishing), which, from its exit out of the lakes that give rise to it, has a course of about 90 miles. From the ground sloping with more rapidity upon this side of the mountain chain than on the other, the water-courses must be considerably steeper. Mr Barrow, in his *Excursions in the North of Europe*, speaks in glowing terms of the "snow-capped mountains, the fir-clad hills, the lovely valleys, the clear and limpid streams, the clearer lakes, and unfathomable fiords." The extraordinary clearness of the water has been a subject of remark by all travellers, and has no parallel in any other country; neither has it been satisfactorily accounted for. It may possibly be owing to the purity of the water itself, the clear sky, and clear white sandy bottom which often prevails in the fiords. Sir Arthur De Capell Brocke makes the following observations upon the singular clearness of the water:—"As we passed slowly over the surface (of the fiords), the bottom, which was in general a white sand, was clearly visible, and its minutest objects, when the depth was from 20 to 25 fathoms. During the whole course of the tour I made, nothing appeared to me so extraordinary as the inmost recesses of the deep thus unveiled to the eye."

The forests of Norway, as is well known, are large and numerous; but they do not appear to be so extensive as those of Sweden. In the southern parts of Norway, indeed, and up as far as Trondhjem the supplies of timber are considerable; but to the north of the latter place, and along the sea-coast, as well as on the mountain ranges, wood is not plentiful, many parts of the country being perfectly destitute of it. Norway, however, from the district of Trondhjem southwards, may be considered as a country abundantly supplied with gigantic forests of magnificent trees, amongst which the pine, birch, and aspen are the most celebrated and the most valuable to the inhabitants.

The prevailing rocks found in Norway belong to the Geology. primitive and transition series. The west coast is wholly composed of primitive rocks, gneiss and mica-slate greatly predominating. Secondary rocks occur but rarely, and alluvial deposits are not so abundant as in many other less extensive regions. Granite is rare. When it appears, it is frequently in veins traversing the primitive stratified rocks, or running parallel with beds or strata; and sometimes it is found spread over the surface of mica-slate, as at Forvig; or irregularly associated with clay-slate and diallage rock, as in the island of Mageroe. But by far the most abundant rock in Norway is gneiss, all the others of the primitive

¹ *Field Sports of the North of Europe*, vol ii., p. 295.

Norway. series appearing to be subordinate to it. Extensive tracts of country, and long mountain ranges, seem to consist almost entirely of gneiss. In some parts it abounds in veins of rose and milk quartz, in iron ores, in garnets (sometimes the precious, but most frequently the common garnet), and other minerals. Mica-slate, however, which rests upon and alternates with the gneiss, is far from being so generally distributed; as is also the case with the clay-slate. In some places steatite occurs in beds, and is quarried in slabs to be used for different purposes. Quartz rock, various hornblende rocks, and limestone occur in beds subordinate to the gneiss and mica-slate. One side of the valley of Shalheim, situated between Bergen and Sognefiord, is bounded by hills of snow-white quartz, which are almost bare, and present mural precipices having a very singular appearance at a distance, from their shining white colour. Gabbro or diallage rock occurs in great quantities, connected with clay-slate, in the island of Mageroe and in other parts of Norway. The class of transition rocks contains, besides graywacke, alum, slate, limestone (sometimes combined with tremolite), and other rocks well known to mineralogists as belonging to the following eruptive series:—Granite, which sometimes contains hornblende; syenite, which contains a beautiful labradorite, and often crystals of the gem named zircon; porphyry, and associated with it various trap rocks allied to basalt and amygdaloid. All the mountains, and especially those of the south, contain a great number of minerals much prized in collections, and of metals valuable to man, amongst which may be mentioned gold, silver, iron, copper, cobalt, and lead. The mines of silver in Norway are situated at Königsberg; but although they once afforded rich returns, they now scarcely repay the labour bestowed on them. Large masses of native silver have been found here; one of them, about 6 feet long by 10 inches in diameter, is now in the museum of Copenhagen, weighing upwards of 500 lb. The Königsberg mines abound with mineralogical curiosities, of which the most remarkable is native electrum, a natural alloy of gold and silver. There is a gold mine at Edswold, in the district of Rommarge, and mines of lead and silver in that of Jarlsberg; but they have not been wrought to any extent. The copper mines of Norway are chiefly situated in the northern division of the kingdom. The most considerable are those at Alten, situated in the 70th parallel of latitude, and worked by a company of Englishmen; and at Röraas, on the Swedish frontier, in Lat. 62. 35. N.; the latter of which were discovered in 1644. These consist of three mines, called the Storvuitz, Röraas, and Ejda. The ore both of the Alten and Röraas copper mines is of the same character; the veins not rich, but numerous and powerful. Copper is supposed to exist to the northward of Röraas, in various parts of the mountain range which divides Sweden from Norway. The other copper mines are from 15 to 20 leagues from Trondhjem, at Quikne, Laeken, Selboe, and in the district of Christiania at Fredericksgrave or Folede. The principal iron mines are situated in Southern Norway; and of these the most distinguished are those of Arundal and Krageroe. The mines of Arundal are celebrated for the richness of their mineralogical treasures. Many of these are rare, such as botryolite, datholite, wernerite, scapolite, and moroxite; besides abundance of epidote, actinolite, cocolite, and colophonite. The ore (magnetic iron ore) is found in beds of gneiss, of which the country is chiefly formed. The total quantity of iron ore obtained annually does not exceed 30,000 tons, but it is of the finest quality. The total produce of copper varies from 400 to 500 tons. The mines of cobalt, which are worked at Modum and Fossum, are extensive, but not very deep. There is a mine of plumbago and black lead at Engledal. The mines of alum, which are worked in the mountains of Egeberg,

near to Christiania, afford not only a sufficiency for the consumption of the country, but some for exportation. Norway possesses quarries of granite, marble, millstone, whetstone, slate, and clay. Granite is exported to Holland, and marble and other minerals to Denmark.

Some valleys in Norway give abundant indications of their having been lakes of fresh water, which were either gradually drained as the land became elevated, or, bursting the barriers that confined them, suddenly laid their basins dry. Mr Laing describes one of these in the following passage:—"On ascending the steep which bound the flat alluvial bottom of the valley on each side, and which consists generally of banks of gravelly soil, one is surprised to find a kind of upper terrace of excellent land, cultivated and inhabited like the bottom, and consisting of the same soil, a friable loam. This terrace rests against the primary rocks of the fjelde, which are here limestone, marble, and gneiss, or rock of the micaceous family, of which the laminae are singularly twisted and contorted; and the terrace has evidently been the bottom of an ancient lake, which has been bounded by these fjelde ridges." The same traveller gives an account of one of those ancient sea-beaches, which, in other countries besides Norway, are calculated to arrest the attention and excite the wonder of the observer of nature. He is speaking of the Snaasen Vand, a lake some 60 or 70 miles, north from Trondhjem. "About 7 miles inland from the present sea-strand, at the head of the fiord, and about 60 feet above the present high-water level, there is an ancient sea-beach of a very remarkable character. About the house of Fossum, and 40 feet higher than the lake of that name, the sea-shells are so abundant that they might be applied to agricultural purposes, and they lie close to the surface." At another place in the neighbourhood there is a large bed of shells, which have been used in mending the road for a considerable distance towards Snaasen Vand. "They are entire; the upper and under ones of the mussel, cockle, and clam are united, and the mussels grouped together, as in the living state; so that this bed has clearly been the spot upon which the animals lived." From these and other indications, it is concluded that a shore, in a direction nearly parallel to that of the present one of the Trondhjem Gulf, and on a level at least 60 feet higher, has existed at a recent geological period. These beds are not covered with any thickness of decayed vegetable soil, and the shells retain in part their natural hue and enamel. The land, therefore, has been elevated at no very distant period; at what rate per century has not been determined as to this side; but the Swedish philosophers assert that the change of level in the Gulf of Finland is at the rate of $4\frac{1}{2}$ feet in a hundred years. Such could not have been the case on the shores of Norway washed by the North Sea, for the relative positions of known points upon the line of the sea-shore, to the present level of the sea, are by historical evidence ascertained to have changed little if any during a thousand years. The change of level may have been local, or it may have gone on more rapidly at one time than at another.

Earthquakes have been repeatedly experienced in Norway. History records one which occurred at Trondhjem on the 18th of July 1686, and another on the 1st of April 1692. On the 14th of September 1344, the River Guul disappeared in the earth; and on its bursting out again destroyed forty-eight farms and 250 human beings. About the same time a great earthquake took place in Iceland. Indeed the whole aspect of this country bears evidence to the fact, that at some period, or more probably at different periods, its surface has been elevated, depressed, and shattered by great convulsions.

From the general elevation of the land, the climate is of course rendered more severe than would naturally be-

Norway.

Ancient lakes, &c.

Climate and soil.

Norway. long to a country under the same parallel, the general elevation of which was more nearly on a level with the ocean. The winters are long and very cold; but, as in all northern climates, their length and severity are in some measure compensated by the great heat, and consequently rapid vegetation, in summer. Towards the east, and in the interior, the winter is longest, the cold, generally speaking, always increasing towards the north. The effects of the sea-breezes upon the general temperature of the coasts of all countries are well known. Winter, however, is very pleasant and salubrious; for although the air is cold, it is dry and bracing, not damp and raw. But the western part, especially about Bergen and along the coast, is proverbially rainy, owing probably to the high mountains, which attract the clouds wafted from the ocean. But the country behind this barrier is on that account particularly dry, perhaps somewhat too much so. In Norway the weather is in general more steady than in Britain; it is either good or bad for considerable periods. The summer season is delightful, and very warm. In narrow glens it is too hot during the middle of the day; but the morning, evening, and midnight hours are charming, and peculiar to this country. The sun is below the horizon for so short a time that the sky retains the glow, and the air the warmth and dryness, which are as grateful to the eye as they are pleasing to the feelings. A little north of Trondhjem it continues above the horizon for the twenty-four hours in the height of summer. Summer lingers long in this country; and, in general, it is an unbroken series of beautiful days. The disagreeable season is the spring (April and May), when, in the transition from winter to summer, the snows are suddenly melted, and the ground is rendered uncomfortable for travelling. Damage is sometimes done in this season by the rapid swelling of the torrents and rivers. When the white covering of winter disappears, vegetation bursts forth at once, and advances with astonishing rapidity.

The mean annual temperature at Christiania is $41^{\circ}5$, the winter being $23^{\circ}2$, the summer $59^{\circ}8$. At Bergen the mean annual temperature is above 5° higher than at Christiania, being $46^{\circ}8$; and while in the summer months the temperature is nearly the same, the winter months at Bergen are, on an average, not less than 13° warmer. At Trondhjem, in Lat. 63.26° N., the mean annual temperature for the year 1826-7 was $40^{\circ}8$, being in each month as follows:—November, $33^{\circ}1$; December, $31^{\circ}3$; January, $18^{\circ}5$; February, $16^{\circ}7$; March, $27^{\circ}5$; April, $42^{\circ}3$; May, $56^{\circ}3$; June, $62^{\circ}4$; July, $57^{\circ}9$; August, $54^{\circ}7$; September, $51^{\circ}1$; October, $38^{\circ}7$. At Alten, in Lat. 69.57° , the average temperature for eleven years (1837-1848) was at 9 A.M. $34^{\circ}50$, and 9 P.M. $32^{\circ}83$; mean, $33^{\circ}66$. The mean temperature of February, which is decidedly the coldest month, is $15^{\circ}4$; and of August, which is usually the hottest, $54^{\circ}3$. This range, however, is small compared with the actual extremes on particular days; for we find in 1848 the maximum at $86^{\circ}9$, the minimum at $-20^{\circ}2$. It is rarely, however, that the mercury falls below zero; whilst there is not perhaps another part of the earth's surface on this parallel where the mercury does not freeze in winter. The fall of rain and snow here in 1848 was 17.19 inches. The gulf-stream exercises an important influence upon the climate of Norway. Taking its rise in the Gulf of Florida, it proceeds northwards and eastwards, until it breaks on the shores of Europe and Northern Africa, a portion of it striking the western coasts of the British Isles, and being prolonged to the coast of Norway, imparting warmth to water and to land, and effectually repelling the invasion of floating ice, with which the coast of Norway would otherwise be continually menaced. It is a remarkable fact, that the smallest piece of drift ice is unknown on any part of the Norwegian coast, though it extends to Lat.

71. N.; while off the coast of North America they are occasionally seen as far south as Lat. 41° N.

Norway.

The luxuriance of vegetation being abridged by the length and severity of the winter, the soil is thus indirectly rendered comparatively sterile. In America the immense forests are continually enriching the mould with their decaying foliage; but in Norway the paucity of alluvial tracts, the prevalence of rock, seldom far beneath, and often forming the surface, together with the want of vegetable decomposition, materially detract from the quantity as well as the quality of the soil. In some parts it is very rich; and the valleys, in particular, are celebrated for their luxuriant fertility. But much of the soil is thin, and obstructed by rocky knobs rising above its surface, and interfering with the labours of the husbandman. "I have not, indeed," says Mr Laing, "seen in Norway twenty acres of arable land in one field, without some obstruction from knobs of stone." The vegetation of the west coast of Norway is very similar to that of Britain, but in the south and east there is found a completely different flora, approximating to that of Denmark and Germany. The cause of the remarkable difference between the flora, and also the fauna, of the two coasts, may probably in part be referred to the absence of tides on the south coast. This circumstance seems to exercise an important influence on the character of the natural productions of the country; and we the more especially refer to it, as it seems to have been hitherto entirely overlooked by naturalists. At Bergen the tide falls 6 or 8 feet, but on the south coast it does not fall 6 inches.

"In Norway," says Mr Laing, "the trees of the pine tribe are called *furu* and *gran*. *Furu* is our pine (*Pinus sylvestris*), and *gran* is our fir (*Pinus abies*); the one is the red wood, and the other the white wood of our carpenters. There are whole districts which produce only *furu*, others only *gran*; and this seems not exactly regulated by latitude or elevation. The zones at which different trees cease to grow appear to be a theory to which the exceptions are as numerous as the examples. In Romsdal amt, at Fanne Fiord, near Molde, in Lat. 62.47° N., and with a medium temperature of only 4° of Reaumur (41° of Fahrenheit), pears, the bergamot, gravenstein, and imperial, and also plums, come to perfection; and the walnut tree often bears ripe fruit. Hazel and elm in the same amt form continuous woods, as at Egerdal. Yet the *gran* disappears altogether, although in the same degree of latitude it grows at an elevation of 1000 feet above the sea in the interior of Norway, and even in Lat. 69° in Lapmark. It has been found a vain attempt to raise it in Romsdal amt, a locality in which the following trees and bushes grow readily:—Canadian poplar, balsam poplar, horse chestnut, larch, elder, yew, roses of various sorts, lavender, box, laburnum, white thorn, and ivy. Larch brought from Scotland appears to thrive. There must be something in the nature of the plants, not connected with elevation or latitude, that determines the growth of the *gran* and *furu*." Wood grows in sheltered situations in Nordland and Finmark, as far north as Alten Fiord (Lat. 70°), but of diminutive size, and in limited quantity. Trees in the valley of the Namsen are large enough for building material and the masts of ships. Laing remarks, that he "did not expect certainly to be charmed with the crops in the sixty-fifth degree of north latitude; but the vegetative power, whatever be the cause, is more vigorous here than in the north of Scotland. Some of the largest establishments of saw-mills in Norway are supplied with trees from the forests around the Snaasen Vand. Of ordinary productions,—as rye, oats, bere, flax, hops,—there appeared to be great crops. This may well be in a soil and climate which raises such noble forests. Behind the house I inhabited is a standard cherry-tree bearing ripe fruit. It would be a rarity in Scotland to raise

Natural
productions.

Norway.

them unless against a wall, even eight degrees of latitude south of this." Here Mr Laing found hops cultivated as a crop, while flax ripened so as to be fit for seed. The mountain and common ash are here scarce; the aspen, wild cherry, birch, and the pine tribes, being the trees, and the juniper, wild raspberry, and wild rose, the bushes which generally prevail.

The country south of the Namsen may be considered as capable of producing, in favourable situations, the grains and fruits of England, and these, too, often in the highest degree of perfection. Most kinds of fruit are abundant, but the greatest favourite is the cherry. The crop of cherries is scarcely ever known to fail; and in proof of the abundance of this fruit, it may be mentioned that the Norwegians preserve it in great quantities, and use it in many culinary operations. Amongst the fruits growing wild are strawberries, raspberries, cloudberries, cranberries, and various other kinds of berries. The three first mentioned are considered as delicious, and they are eaten both when freshly gathered, like cultivated strawberries, and after being preserved.

Zoology.

The animal kingdom of Norway requires some notice. As population has increased, the wild animals have of course gradually disappeared, and the bear and the wolf are no longer the terror of the traveller, as they were wont to be. In November the bear retires to some sheltered hole in the rocks of the Fjeld, and remains in a state of inactivity, without food, it is said, until April. Indeed many of the smaller animals—the field-mice, the lemmings, and, Mr Laing conjectures, many of the birds—pass the winter in this climate in a state of occasional torpidity. The wolves are not so dangerous animals as those of the south of Europe. They rarely attack a man, but they will carry off a dog at his side; and they often commit serious havoc amongst the domestic animals. The loss of sheep, calves, cows, and foals, in certain parishes, during the season when they are at pasture, is sometimes immense. Bears also commit depredations of the same kind, but not nearly to the same extent as the wolf, which, when he gets into a herd, bites and tears all that he can overtake. Many horses may be seen scarred by them. The elk is now rarely met with, and in all likelihood has entirely disappeared from this part of Europe. It is described in former times as a magnificent animal, being often seventeen hands in height, and sometimes exceeding in size the largest horse. The glutton or wolverine, so called in America, is reckoned a Norwegian animal. Its total length is not more than two feet and a half, and it flies from the face of man. It feeds chiefly upon beasts which have been accidentally killed; but it will hunt small animals, such as meadow-mice, marmots, and the like, and occasionally attack disabled animals of a larger size. Although not fleet, it is very industrious, and does great injury to the small fur trade in the northern parts of Europe. The rein-deer, which is found in considerable numbers on the Hardanger Fjeld and the Sogne Fjeld, and the diversified qualities of which are so beautifully adapted to the bleak and inhospitable regions in the north of Norway, will be found described in the article LAPLAND. The author of *Notes on a Yacht Voyage to Hardanger Fiord* mentions falling in with a herd of from three to four hundred rein-deer when descending from the Folgefonden. "The whole herd was soon out of sight. In the distance it resembled a vast moving cloud against the snow, with a small dark mote in front. The guide said they were not often seen congregated in such large numbers." The beaver, although not extinct, is rare, and lives solitary, not, like the American beaver, in society. A particular kind of dog, with a remarkably fine, soft, and glossy fur, is bred for its skin, which is made into pelisses for winter wear. Besides the wild and tame rein-deer, red deer are pretty numerous in some districts. The fox and

Norway.

the lemming are abundant in some parts, particularly in the north. A multitude of birds inhabit the coasts of the ocean, and Norway furnishes a considerable part of the eider-down, so well known to the luxurious in couches. Game is plentiful; the principal birds being called the tydder, roer, ryper, and jerper. The tydder is the bird known of old in Scotland by the name of capercaillie, and which became extinct in that country, but has been introduced again of late years by the Marquis of Breadalbane and other noblemen. The cock is a noble bird, of the size of a turkey-cock, with a bill and claws of great strength. The roer is the female, and in size, plumage, and appearance so different from the male, that it has received a different name in the language. The ryper is the same as the Scottish ptarmigan, but larger and better clothed. Its flavour, however, is inferior to the game of the Scottish hills. But the jerper is a more delicate bird for the table than any of our game. It is of the grouse species, and about the size of a full-grown pigeon. The silence of the forest solitudes is occasionally broken by the sweep of the eagle's or the heron's wing; but the traveller in Norway is generally struck with the limited number of small birds which he meets in the course of his ramblings. Magpies, the Royston crow, and swallows, are common; but the lark, linnet, thrush, blackbird, robin, and some others common to Great Britain, are little known here. Mr Barrow mentions hearing the cuckoo, not far from Røraas, at an elevation of 3000 feet above the level of the sea. Hares and squirrels are in considerable abundance; and there are some other quadrupeds and birds no strangers in the country, but they are of too little importance to require any particular mention. Amongst domestic animals may be mentioned the horse, goat, sheep, and cow; the goose, the duck, and the turkey, which are also found wild. Of horses there is a small breed very general in Norway, and another of a larger size, which is much esteemed for its swiftness and sureness of foot. "These Norwegian horse are beyond all praise," says Mr Laing; "they scamper down hills as steep as a house roof, and in going up hill actually scramble. They have no objection whatever, if you have none, to any path or any pace; they are the bravest of horse kind." All travellers speak of them in similar terms. They are fed entirely upon hay, which, although merely withered grass, appears to be more substantial than ours, from the wind and powers of the horses, which live upon nothing else. The sheep are shaped like deer, having long legs and small muzzles. Numbers of goats and cows are kept, the milk which they yield being very rich and highly esteemed. Fish abound in the seas, lakes, and rivers of Norway; and the inhabitants not only derive a considerable portion of their subsistence from fishing, but it also forms an important article of export. Salmon-fishing in Norway has become a favourite pastime with many of our countrymen. Amongst the insects, the gnat, or rather mosquito, is found exceedingly annoying. They are in greatest abundance and most venomous in the north. The *Furia infernalis*, so called from the dreadful effects which follow from its bite, frequents the marshes or boggy grounds. The acute pain and inflammatory swelling which its bite produces are removed by a curd poultice, which is said to be an infallible cure. The entomology of the south of Norway is very similar to that of the south of England, whilst that of the west resembles the entomology of Scotland.

The principal products of the Norwegian farm are,—oats, Agriculture, wheat, bere, hops, flax, a kind of bearded spring grain, with potatoes; and a large portion of every farm is set apart to grow grass for the cattle and horses. The grass for the most part is natural, sown grasses for hay being very little cultivated. The land, after a bere crop following potatoes, is left to sward itself with natural grasses for four years, and to form the hay land; so that the proportion of grass to

Norway. arable land is much greater than in our farms. The natural grasses do not attain any length, and they are shaven as close to the ground as a bowling-green. The fields are not what is called top-dressed, as with us. The scythe in use is much shorter in the blade than that of Great Britain, and it answers the purpose much better. Potatoes have been much cultivated since 1812 and 1814, when bad crops, and the war then raging, reduced many to the use of bark-bread. A small inclosure for hops is attached to every farm-house; but garden vegetables are little used. Probably the short interval between winter and summer allows little time for attending to any but the essential crops. The hop flourishes with little attention under the sixty-fourth parallel; a striking fact, seeing that this plant is delicate and precarious in the south of England. In farming operations, ditching, draining, and clearing land of vegetable and other obstructions, are prosecuted with great spirit and success. Agriculturists are continually adding to the quantity of arable land in the country by thus redeeming the soil from its original wild state. However, from causes already mentioned, Norway is not capable of furnishing the means of subsistence to any considerable population. Generally speaking, only the glens of the country are inhabited. On the dividing ridges there is little or no cultivation, and, indeed, no soil to cultivate, but only rounded masses of gneiss and micaceous rocks, with juniper, fir, aspen, birch, and beech, growing where they can amongst the stones.

Mr Laing gives a minute account of a Norwegian farm rented by a Scotchman; and as he considers it "fitted to be the representative of a large portion of the estates into which this country is divided," we shall abridge his description. Each farm may be considered as consisting of three divisions. The first is the infield, or what we should call the mains, or home acres, inclosed for the crops and the best hay. The next is the mark or outfield, also inclosed, and affording the out-pasture for the cattle. Parts of it are occasionally fenced off, and broken up for grain, and, when exhausted, are left to sward themselves; so that when the cattle are sent to the fjelde in summer, some hay is got from the mark. There is often a still rougher piece of ground divided from the mark, as a range for goats and young cattle, called the out-mark. The third division is the seater. This is a pasture or grass farm, often at the distance of 30 or 40 miles up in the fjelde, to which the whole of the cattle and dairymaids are sent for three or four months in summer. The huts on these seaters are substantial buildings, with every accommodation necessary for the dairy, and butter and cheese are accordingly made in very considerable quantities. "The farm of my countryman," says Mr Laing, "consists of 1276 mælings, or 290 English acres; but this does not include the seater, which happens here to be on the hills immediately behind the farm, is covered with fine trees, and is of a defined boundary, extending about a Norwegian mile (7 English miles) in circuit. On the measured land, 148 acres are cleared; but, being farmed in the Norwegian style, one-third only bears crops of corn and potatoes. The remainder is always in grass or hay, for the winter support of the cattle. It is natural grass, not top-dressed with manure, and is mown when not above the length of one's finger, so that the proportion of arable land that must be given up to keep the cattle in winter is enormous. It is the system of farming in this quarter; 142 acres outside of the 148 infield are half cleared, being fenced off and ploughed in patches. It bears good grass, but is encumbered in some places with brushwood and stones."

"This farm supports twenty cows, seven horses, and a score or two of sheep and goats. The accommodation for cattle is excellent. They stand in a single row in the middle of a wide house, with partitions between each, and room before and behind greater than is occupied by the

animal itself. The cow-house is lighted by glass-windows on each side. The cattle stand on a wooden floor, below which is a vault, into which the dung is swept by a grated opening at the end of each stall." All the cow-houses in Norway are constructed on this large and convenient scale; and neither cows nor horses require litter, which is a great saving of fodder. Besides, they are kept perfectly clean with comparatively little trouble. The value of a farm in Norway depends very much upon the locality. In Forster's *Norway* (Appendix), one containing about 300 acres of cultivated land, besides some bogs capable of cultivation, and a good little forest of different kinds of wood, is mentioned as having cost about 12,000 dollars, or about L.2200 sterling. Twenty years were allowed to discharge the purchase-money, the tenant in the meantime paying a rent of L.4 per cent. Many farms, however, of like extent, may be had for one-half, or even one-third of this sum. The one mentioned by Laing was considered worth about 4000 dollars.

"The harvest-work here," says Mr Laing, "and I believe all over Norway, is well done; and parts of their management might be adopted with advantage in our late districts, where so much grain is lost or damaged almost every autumn by wind or rain. For every ten sheaves, a pole of light strong wood, about the thickness of the handle of a garden-rake, and about 9 feet in length, is fixed in the ground by an iron-shod borer; it costs here almost nothing. A man sets two sheaves on the ground against the stem, and impales all the rest upon the pole, one above the other, with the heads hanging downwards." This is certainly a mode very superior to ours; and they have likewise a better way of cutting it, by which little of the grain is lost. But for an account of this process, and other farming operations, we must refer to Mr Laing's work (pp. 96, 106).

The breed of cattle in Norway is fine-boned, thin-skinned, and kindly-looking; the colour is generally white, sometimes mixed with red, but seldom entirely black. The head and muzzle are as fine as in our Devonshire breed. There is so little coarseness about the head or neck of the bull, that the difference between him and the ox is less observable than in our breeds. The cattle are all very carefully attended to, and form an important branch of the husbandry, as dairy produce enters much into the food of every family, and is more certain in this climate than that of grain. The cows, sheep, and goats are more tame and docile than they are in Britain, from the constant care and attendance bestowed on them during the long period which they must stand within doors; and the Norwegians are remarkably kind to their domestic animals. Goats are a favourite stock, and on every farm appear to be much more numerous than sheep. The goat will eat and thrive on the shoots of the dwarf birch, beech, and young fir; but the sheep will not, and in winter it requires some hay. The goat then gets dried leaves and shoots of the beech, which only cost the trouble of collecting and drying them.

Irrigation is carried on in many parts to an extent quite unknown in this country. Hay being the principal winter support of live stock, and both it and corn, as well as potatoes, being liable, from the shallow soil and powerful reflection of the sun's rays from the rocks, to be burned and withered up, the greatest exertions are made to bring water from the head of each glen, along such a level as will give the command of it to each farmer at the head of his fields. This is done by conducting water in troughs made of the half of a tree roughly scooped out, from the highest perennial stream amongst the hills, through woods, across ravines, along the rocky and often perpendicular sides of the glens; and from this main trough lateral branches shoot off to each farm. The farmer distributes this supply by moveable troughs amongst his fields, watering each rig successively. The quantity of land traversed by these artificial water-courses is very great.

Norway.

Norway.

In winter, when agricultural operations are suspended, the Norwegian employs himself in making all the implements, furniture, and clothing, which his family may require; thrashing out the crop, attending to the cattle, driving about to fairs, or paying visits. The heaviest of his occupations is driving wood out of the forests, or bog-hay from the fjeld where it is made in summer by those who attend the cattle. The distillation of potato-brandy was, until very lately, general all over Norway, every common bonde or peasant proprietor distilling his own few barrels. The vice of drunkenness, however, had become so flagrant, that it was considered necessary by the Storting to place very stringent restrictions on the sale and manufacture of spirits; and now private stills are strictly forbidden, and spirits are only allowed to be sold in the towns. The improvement in public morals, in consequence, has been very marked. In the valley of the Miosen Mr Brace made inquiries as to the general morality of the bonders of the province, and learned that intoxication was certainly very much diminished since government had made it so difficult to get brandy, and that altogether there was a great progress; which doubtless is the case in all other districts.

The thrashing machines in general use amongst agriculturists are similar in construction to those of Scotland; and some have grinding machinery attached to them. There is an institution of a very peculiar nature, which is quite common all over Norway. In this country there are no merchants equivalent to our corn-dealers, nor are there any weekly markets held for the sale of grain. There are no middle-men between the grower and the consumer, and any surplus grain which the farmer may have is stored up in what may be called corn magazines, which are just large warehouses erected in various parts of the country, as the necessities of the inhabitants require them. What grain the farmer thinks he will not require he conveys in sledges to these places, and for every eight bushels which he deposits, he receives nine at the end of twelve months; in short, he lays it out at interest, and has an increase of one-eighth per annum. If, however, he has none deposited, or overdraws, he pays for the quantity received in loan at the rate of one-fourth of increase per annum; so that for every eight bushels which he takes he pays back ten at the end of twelve months, or at that rate for whatever time he may have the loan. This is, in fact, a savings-bank for corn, and is probably the most ancient of these institutions. The small profit which occurs upon these transactions defrays the necessary expenses of building and keeping up the magazines, which are entirely under the management of the bonder or peasant proprietors. In Norway the bulk of the farmers have no rent to pay, the property being their own; the articles which their farms produce constitute nearly the whole of the food or raiment which they and their people require; and there are not, as in other countries, considerable masses of population in towns and villages, who, not being producers of food themselves, must obtain it from those who are; so that the farmer is less dependent upon money-bringing crops than is the case with us. If he raise what is sufficient for his own household consumption, with a little surplus for sale to purchase a few luxuries, all the purposes of farming are served with him.

State of property.

Property in Norway is held by what is called the udal or odel system of rights, not from any superior, not even from the king, but, as the possessors proudly express it, by the same right by which the crown itself is held; consequently there is no acknowledgment, real or nominal, as feu-duty or reddendo, paid. In this country all lands are theoretically said to be held from the king; and, according to Sir Edward Coke, we have no allodial lands. In Norway estates are allodial, the absolute property of the owner; they are therefore possessed without charter, and are subject to none of the burdens and casualties affecting land

held by feudal tenure direct from the sovereign, or from his superior vassal. There is, in short, a total negation of the feudal principle; there is neither superior nor vassal; so that the military service which the latter paid to the former in consideration of the land which was granted appears never to have existed in Norway; and as this constituted the foundation of the law of primogeniture, so where such service was entirely unknown, there was no necessity for that law, which consequently remained equally unknown. In all feudal countries the eldest male heir has to pay an acknowledgment to the feudal superior on his entering as vassal in the land. But udal, or noble land, as the word signifies, not being held for military service to a superior, no *delectus personæ* as to who should inherit it was competent to any authority, and consequently no preference of the eldest male heir could grow into the law of succession to land. Hence the land came to be equally divided amongst all the surviving children, male and female. There appears, however, to be a species of entail connected with the udal tenure. If the udalman in possession should alienate to a stranger, the next of kin has a right of redemption on paying the price of the land. This is called the Odelbaarn's Ret, and all the kindred of the udalman in possession are what is called Odelsbaarn to his land, or, in other words, have a certain right in the order of consanguinity. By recent enactments, this right of redemption has been limited in its exercise to a period of five years; and it is provided that all improvements, as well as the original price, must be paid for.

The equal partition of property amongst children by the udal tenure has prevented the accumulation of property in large masses; but, as might have been expected by theorists, it has not led to subdivisions of estates to an injurious extent. "The division of the land appears not," says Mr Laing, "during the thousand years it has been in operation, to have had the effect of reducing the landed properties to the minimum size that will barely support human existence. I have counted from five-and-twenty to forty cows upon farms, and that in a country in which the farmer must, for at least seven months in the year, have winter-houses and provender provided for all the cattle. It is evident that some cause or other, operating on aggregation of landed property, counteracts the dividing effects of partition among children." In another place Mr Laing says, "The estates of individuals are generally small; and the houses, furniture, food, comfort, ways and means of living among all classes, appear to me to approach more nearly to an equality to one standard than in any country in Europe. This standard is far removed from any want or discomfort on the one hand, or any luxury or display on the other. The actual partition of the land itself seems, in practice, not to go below such a portion of land as will support a family comfortably, according to the habits and notions of the country; and it is indeed evident that a piece of ground without houses upon it, and too small to keep a family according to the national estimation of what is requisite, would be of no value as a separate property. The heirs accordingly either sell to each other, or sell the whole to a stranger, and divide the proceeds. The duty of the Sorenskriver, or district judge, consists chiefly in arranging this kind of chancery business, and all debts and deeds affecting property are registered with him."

The cause which, according to Mr Laing, has prevented excessive subdivision is, "that in a country where land is held, not in tenantry merely, as in Ireland, but in full ownership, its aggregation by the deaths of co-heirs and by the marriages of female heirs among the body of land-owners, will balance its subdivision by the equal succession of children." This is undoubtedly true; and when taken in connection with other facts, may sufficiently explain the case. Mr Laing informs us that the standard of living is

Norway.

Norway. high in Norway; or that the population is much better clothed, lodged, fed, and generally provided for, than our labouring and middling classes in the south of Scotland. The dwelling-houses of the meanest labourers are divided into several apartments, and have wooden floors and a sufficient number of good windows, with some kind of outhouse for cattle and lumber. Their food and clothing are equally good and substantial. Now it seems quite clear that a people habituated to such a standard of subsistence and comfort will not only not suffer their condition to sink indefinitely below it, but by prudence and foresight in the contraction of marriage and the raising of a family, will keep down their numbers considerably within their means of subsistence. In Norway, that condition which secures respectability to a common man is one in which he commands not only all the comforts, but most of the luxuries of life common to the country; and the natural desire of all mankind to keep up caste, to maintain themselves in that station in which they were born, not to decline from it, and fall, as it were, out of the ranks, will operate as a most powerful check upon the minute subdivision of land. There are other causes in operation, to which our circumscribed limits will only admit of our adverting. These are the ancient and confirmed habits of the people, which may be taken into account as a corollary of the preceding proposition; and the absence of impediments, such as fines or alienation, or imposts of any kind, in the way of sale or conveyance. Where such fines exist, the difficulties of re-uniting land which has been subdivided are great and annoying.

The bulk of the population in Norway consists of two classes of landholders: those who have farms larger than they themselves can cultivate, and those who exclusively farm their own estates. The first are called proprietors, a sort of conventional term, equivalent to our esquire; the smaller landholders, who work upon their own estates, are called *bonder*, a term, as appears, nearly equivalent to *feuar* in Scotland. The incomes of the former seldom exceed L.150 or L.200, although there are some who possess as much as L.3000 or L.4000 sterling per annum. The Norwegian valleys are crowded with *bonder* farms, which are very numerous throughout the country, and, with their look of plenty and completeness, may compete with the richest and most beautiful in Scotland. Mr Laing draws a very pleasing and interesting picture of this class of people, whose comfort and happiness may indeed be inferred from a short statement of facts. They are owners of their own little estates, which produce all the necessities of life, and afford a surplus for the payment of taxes and the purchase of luxuries. They are exceedingly well lodged, and the families live abundantly; the manner of living, indeed, is pretty much the same amongst all classes. These, and the comfortable assurance that in case of death the *udalman* leaves his wife and family provided for, are certainly calculated materially to promote human happiness. "This class," says Mr Laing, "are the kernel of the nation. They are in general fine athletic men, as their properties are not so large as to exempt them from work; but large enough to afford them and their households abundance, and even a superfluity, of the best food."

Besides the *bonder*, or agricultural class, properly so called, who occupy all the most fertile lands in the country "from the shore-side to the hill-foot," whereon corn will grow, there is another class called *fjeld bonder*, who form a connecting link, as it were, between the class above described and the wandering *Laplander*. They also possess land, and have houses which, although small, are comfortable; but being above the level of the corn-growing country, their situation is not so favourable, nor is their condition equal to that of the other small proprietors. The *fjeld bonders* are "the hewers of wood and drawers of water" in

Norway; but they still possess property in cattle as well as in land, and they are described as extremely hardy and active, and as having more robust frames than the agricultural *bonder*. There is yet another class of the population which is altogether distinct from any of the preceding, consisting entirely of fishermen, whose social condition must be considerably inferior to that of the others.

In the provinces of Nordland and Finmark, which occupy the northern part of Norway, beyond the River Namsen, agriculture is but a secondary business, and fishing may be said to occupy most of the attention of the inhabitants. Indeed, a Norwegian writer says, that were it not for the Norwegian fishery, the whole of Finmark and a part of Nordland would be inhabited only by nomad Finns, and the towns all along the coast would languish and disappear. The crops of grain are too inconsiderable and precarious to afford them the means of subsistence, and the riches of the deep are brought in as a compensation for the poverty of the land. The winter fishery in the Lofoden Islands, from the middle of January to the middle of April, and the summer fishery over all the coast, which in some branch or other gives employment for the remainder of the year, furnish the inhabitants with the means of purchasing the necessities which they require.

The *Oxonian in Norway*, by the Rev. F. Metcalfe, published in 1856, gives a very complete account of the Lofoden fishery; and from that work we extract the following particulars:—The fishermen begin to arrive in open boats from all parts of Norway soon after New Year's Day, and take up their positions along the coast, from Balstad on the W., to Bretnesnes on the island of Great Molle on the E. In each boat there are generally five men, one of whom commands and takes the helm. At Henningsvær, a favourite station, as many as 900 boats congregate; and it is computed that there are at least 3500 boats, giving an aggregate of 21,000 men, employed exclusively in fishing. Besides these, there are numberless *jaegts* and *jagts*, belonging to merchants from far and near along the coast, which come to buy oil and fish, and sell groceries, &c. At Svolvær alone there were no fewer than 140 of these vessels. The fishermen live in huts along the shore, which, together with the permission to fish, they hire of the proprietors of the adjoining land at certain rates fixed by government. If the morning is fine and the weather suitable, the government officers appointed for that purpose hoist the requisite signal, and the boats go out and set their nets and lines generally at right angles to the run of the coast. If the weather is bad, no signal is hoisted; and every one venturing out under those circumstances is liable to a fine of 5 dollars, and to have all his fish seized. Most of the day is consumed in fishing with a hand-line and in taking up the nets and long lines. On getting to shore, the fish are gutted and hung up to dry on poles and cross-bars, which they hire of the proprietors along the coast. These are stock-fish (so called because they are dried on stocks or poles), and are unsplit. Others, which are sold to the owners of the *jaegts*, are split open, salted down, and packed flat in the holds of these vessels. On obtaining a cargo, they leave for home; and on arriving there, the fish are taken out of the vessel, washed, and dried upon the rocks. These are *klip-fish*—i.e., rock-fish. The laws of Norway are very stringent regarding the preparation of the stock-fish. None are allowed to be taken down before the 12th of June, nor are any allowed to be hung up after the 14th of April. There is a fine of 2 dollars on every hundred fish taken down or hung up before or after the above dates respectively. Everything is managed according to strict rule, and under the surveillance of government officers. During the period of the fishery no steamer is allowed to come near, for fear of driving away the fish. All the fish caught after the 14th of April are prepared as *klip-*

Norway.

fish; but the fishing is virtually over then, and the men leave the Lofodens, returning, however, in the course of the summer to take away the stock-fish. The cod-liver oil so extensively used in medicine is prepared from the livers, which are put into barrels brought from home for the purpose, or sometimes sold to merchants on the spot. The best oil is that which exudes from the natural fermentation of the liver. Cod-liver oil is not obtained solely from the cod-fish, but also from others, as the shark, the ling, and especially the sei or coal-fish, its liver being richer in oil than that of the cod. It is caught in large quantities in summer, especially in the Bay of Varanger. Cod-liver oil costs on the spot from 5 to 6 dollars the barrel of 120 pots, and a wine-bottle holds about three-fourths of a pot; so that, in round numbers, at the highest price, it costs about 1s. the imperial gallon.

All the towns export fish. Bergen exports more than one-half the stock-fish; but of late the Romsdal towns, as they are called, have become dangerous rivals to it in the klip-fish trade. Half the oil goes from Bergen. There is still a heavy export duty on all kinds of fishery products. About L.6000 are also raised annually by the duty on salt, the greater part of which is used in curing the fish. Until 1851, a tithe of all the fish and oil was paid to the church of the district; but instead of this tax, which was very vexatious, and led to numerous disputes and much dishonesty, an extra tax of two skillings per waag (36 lb.) is levied on all fish exported; while on oil the additional duty is 12 skillings (5d.) per tonde (30 gallons). The value of the different kinds of fish annually exported is estimated at about one million sterling. The quantities are given in a subsequent table.

Besides these important general fisheries, there is in every creek of the fiords, even at a hundred miles up from the ocean, abundance of cod, whittings, haddocks, flounders, sea-bream, and herrings, caught for daily use and for sale by the seafaring peasantry. The rivers and lakes are likewise well supplied with fish (the former with salmon), which may indeed be said to constitute the basis of a Norwegian repast. Dried and salted fish is sent in great abundance to the Mediterranean, and also to Hamburg and Holland. Lobsters are caught among the rocky islands in immense numbers for the supply of the London market. Anchovies are also caught in prodigious quantities.

Manufactures and commerce.

The manufactures of Norway are too unimportant to detain us long. Wood and fish are the chief produce of the country; and these find their way to every part of Europe, chiefly in Norwegian vessels, which in return bring home whatever foreign articles are required, at the cheapest possible rate of freight. The import duties are very moderate. Before the importer pays his duties, he is allowed to take his goods to his own warehouse and shop, upon giving security for the amount of the duties ascertained by the custom-house officers at landing; he also keeps an account of his sales, and pays the duty every three months upon the quantity which appears to have been sold. This must be of great advantage to the dealer in a country so poor as Norway, since it leaves his capital entirely free for active employment. Coffee, sugar, tea, French brandy, and French and Spanish wines, tobacco, and a limited quantity of spices, are the principal articles for which the housekeeper has to disburse money. The other necessities of life are produced by themselves. Shoes, furniture, cloths, and the like, are all made at home. Looms are at work in almost every house in the country; carding, spinning, and weaving forming constant occupations of the female part of the household. Woollen cloth, substantial but coarse, excellent bed and table linen, and checked or striped cotton or linen for female apparel, are the ordinary fabrics produced. These home-made stuffs, including boots, gloves, and in bad weather great-coats, clothe the greater part of the inhabitants, and more comfortably than is the case with the lower and mid-

dling classes of people in most other countries. The upper ranks, or the people of condition, dress as in other parts of Europe; and as living and lodging are nearly on a level amongst all the respectable classes, the peasant proprietor, and those more wealthy than he is, this wearing of foreign articles by the latter, and home-made stuffs by the former, would seem to constitute a kind of conventional distinction between them.

The principal articles of export are timber, bark, iron, copper, fish, and some others. The principal articles of import are corn; colonial produce; woollen, linen, and cotton goods; wine; brandy, &c. The following is the quantity of fish exported from Norway in the year 1855, viz. :—

Stock-fish.....	tons	16,374	Cod-Liver Oil ...	barrels	78,804
Klip-fish.....	"	22,318	Anchovies	kegs	11,737
Cod Roes.....	barrels	30,668	Salmon, smoked.	lbs.	4,551
Herrings, salted...	"	519,868	Salmon, salted...	barrels	77
Other Fish, salted	"	3,040	Lobsters, live...	number	814,188

In the year 1854, 31,000 quarters of oats were exported, which Mr Crowe states is unparalleled in the annals of the trade of Norway, but is likely to be repeated, as the province of Hedemarken, which is now brought into connection with the capital and sea-coast, is pre-eminently suited for the growth of that cereal. The total amount of cereals imported in 1851 was 631,390 imperial quarters; in 1852, 602,110 do.; in 1853, 567,192 do.; in 1854, 425,975 do.; and in 1855, 492,591 do.

Mr Crowe further remarks that there has been a general increased importation of many articles, attributable to the prosperity of the country and the reduction of duties on a variety of articles entering largely into their domestic economy.

The deals of Christiania have always been held in the highest estimation; a consequence of the excellence of the timber, and of the care with which the sap-wood and other defective parts are cut away. Like many other branches of the trade of Norway, that of preparing wood was formerly fettered by pernicious restrictions; the saw-mills being licensed to cut a certain quantity only, and the proprietors bound to make oath that it was not exceeded. But this absurd regulation no longer exists.

The following is a return of timber and deals of every description, exclusive of deal-ends for splitwood under 20 inches long, lathwood, &c., exported from Norway in the years specified, viz. :—

	Loads.		Loads.
1851 ...	632,727	of which there were sent to Great Britain	165,024
1852 ...	701,462	" " " "	182,879
1853 ...	775,845	" " " "	246,646
1854 ...	743,468	" " " "	236,247
1855 ...	737,557	" " " "	217,915

The amount of wood under 20 inches, called splitwood, exported to Great Britain in 1855 was 40,980 loads.

British manufactured goods are admitted into Norway on moderate duties, and are very generally made use of.

The weights and measures of Norway are the same as those of Denmark. With regard to money, the principal silver coin in circulation (for there are none of gold) is called a species dollar, which is divided into one hundred and twenty skillings. There are also half species, one-fifth species, one-tenth species, one-twentieth, and what is denominated *skillemynt*, or small change—that is, four and two skilling pieces of silver, and also one-half, one, and two skilling pieces of copper. The dollar is worth four shillings and fourpence three farthings sterling at the present rate of exchange. There are, besides, notes of one dollar, half a dollar, and twenty-four skillings, all printed on white paper. The notes of five dollars' value are on blue paper, those of ten dollars on yellow paper, those of fifty on green paper, and those of one hundred on red paper.

The Norwegian finances are in a flourishing condition, the revenue having latterly increased considerably. The

Norway.

Norway. Bank of Norway, which was founded in 1816, has its head-office in Trondhjem, with branches in the principal towns, and is under the direction of five stockholders, with a council of fifteen representatives of the other proprietors. The transactions of this bank are conducted upon a principle totally opposite to that of the Scotch and other banking establishments. It is there considered as a first principle that the bank should hold only available securities, as bills or bonds at a short date, or payable at a short notice, for its issues or advances. The national bank of Norway is therefore a bank for landed property, and discounts mercantile bills and personal securities only as a secondary branch. Its chief business is advancing its own notes, upon first securities over land, any sum not exceeding two-thirds of the value of the property, according to a general valuation made in the year 1812. The borrower pays four per cent. for what he draws, and is bound to pay also five per cent. of the principal yearly. This kind of bank is exceedingly well adapted for the wants of the country; and their paper can scarcely be considered as less secure than their silver.

Army. The Norwegian army consists of some 24,000 troops of all arms. Two companies belonging to each regiment in the Norwegian service are trained to the use of the skidor or skate. This corps, called the skieløbere, move with singular agility and speed, and, whilst skating along with the greatest velocity, perform their military evolutions with uncommon precision. The army is at the disposal of the king, as far as its services can be rendered available in Scandinavia; it cannot, however, be sent beyond the limits of the peninsula without the special permission of the Storting. The king has the nomination of the superior officers of the army, as well as of some few of the first civil officers under the government; that of others rests with the Storting. Norway is governed by a viceroy, appointed by the King of Sweden; Christiania, the capital of the country, being the seat of government. She contributes nothing towards the expense of the Swedish government, beyond a trifling annual allowance to the royal family; but she supports all her own civil and military institutions.

Navy. The Norwegian navy consists of 3 frigates, 5 corvettes, 4 brigs, and 124 gun-boats. They have also 13 steam-vessels of war, of, in all, 1490 horse-power, the largest being of 200 horse-power. Nine of these are employed in the royal mail service, under the command of naval officers. During the summer months three ships are usually commissioned for a summer's cruise with cadets.

The officers of the Norwegian navy consist of a rear-admiral and 6 commodores, 12 captains, 12 lieutenant-captains, 24 first lieutenants, 35 second lieutenants, and 64 petty officers; besides 100 cadets, and 120 artillery cadets. In case of war, every male is bound to serve a certain period either in the army or navy; and there are about 50,000 seamen, whose names are on the registers, liable to serve.

There is a great difference in the pay of the navy and merchant service, the latter being more than double; but, as in our own case, the seamen are far better fed and provided for in the naval service. The merchant seamen are generally engaged either in the transatlantic or North Sea and Mediterranean timber trade, or in the fisheries. They are described as amongst the hardiest and best race of seamen in the world, and accustomed to live on coarse fare, and put up with many hardships to gain their livelihood.

The mercantile marine of Norway has greatly increased within the last few years, as appears by the following return:—

	No. of Vessels.	Tonnage.	Crews.
1851	4496	412,437	24,057
1852	4742	427,234	25,388
1853	4893	454,856	26,545
1854	5129	501,860	28,063
1855	5241	538,964	28,638

VOL. XVI.

Norway. Vessels of all nations now trade with Norway, and her ships are to be met with in every foreign port. Mr Crowe, the intelligent consul-general at Christiania, remarks that "a few years ago, the Norwegian flag was scarcely ever seen beyond the confines of Europe; now it waves in every part of the globe."

Some very interesting and elaborate statistical tables connected with the population and productions of Norway, compiled from government sources, was published in Christiania in 1857. From these it would appear that the following is the total amount of the population in 1855, viz.:—

Province of Christiania.....	643,135
„ Christiansand.....	244,413
„ Bergen.....	242,914
„ Trondhjem.....	227,343
„ Tromsøe.....	132,242
Total.....	1,490,047

The following is the amount of the population at various former periods:—1769, 723,141; 1801, 883,038; 1815, 885,431; 1825, 1,056,318; 1835, 1,194,827; 1845, 1,328,471; and 1855, 1,490,047.

The increase of population has chiefly taken place amongst the agricultural classes; and the additional food raised for their support, together with the advance of the people, is to be attributed partly to additional tracts of land having been taken in, and partly to improved methods of cultivating the old soil.

The kingdom of Norway is divided into five sees or stifts, Political each of which is divided into a certain number of districts, divisions, corresponding to its size and importance, and these again into parishes, of which there are 336 in the country. The dioceses are—Christiania, containing Christiania, the capital; Christiansand, the largest town in which bears the same name; Bergen, containing the large and important city of the same name; Trondhjem, which contains the city of Trondhjem, situated on the south shore of a great fiord of the same name; and Tromsøe, comprising the northern territories of Nordland and Finmark. The stifts are thus distributed:—Christiansand occupies the southern extremity of the country; Bergen and Christiania occupy the former the western, and the latter the eastern side of Norway, where it is widest, extending over its whole breadth in that quarter, and being separated by the great mountain chain; still further north lies Trondhjem, which is succeeded by Tromsøe, the most northerly region of Norway, and of which the reader will find some account in the article LAPLAND. Each district, called a fogderie or bailiwick, is under a foged, who has charge of the collection of taxes, police, and all executive functions in his district. Besides this public functionary, there are military officers, who have official residences in the district; and the amtman, and sorenskriver or judge ordinary. Christiania, Bergen, Trondhjem, and the other large towns in Norway, will be found described under their own respective heads.

The Norwegians enjoy more political liberty than any Political other European nation. The parliament, called the Storting, is chosen by the owners or life-renters of the land, who have attained the age of twenty-five years complete. The minimum value which gives a vote is 150 dollars, or L.33; a value which, from the large diffusion of property, renders the suffrage nearly universal. To render the elector himself eligible as a representative, it is only necessary that he should be thirty years of age, have resided ten years in Norway, and be altogether unconnected with the state. The voters choose electing men, 1 to every 50 voters in towns, and 1 to every 100 voters in counties. The electing men, on a day fixed by law, choose their representatives, and the body thus elected forms the Storting. The proportions of members chosen is founded on the principle that the towns in Norway should as nearly

Norway.

as possible return one-third, and the country two-thirds of the whole body, which must not consist of less than 75, nor of more than 100 members. Each district elects as many substitutes as it elects representatives, to provide against death and other casualties. The Storting is chosen every three years, and is assembled only once in three years, when it sits for three months, or until the business be despatched. The 1st of February is the day of meeting fixed by law. An extraordinary Storting may be convened by the king, but its acts must be confirmed by the next regular Storting. After some preliminary business, such as electing a president, speaker, and secretary, the Storting divides itself into two chambers. One-fourth of its whole number is formed into a second chamber, called a Lagthing, or division, in which the deliberative functions of the legislative body are vested. No bill can be introduced there; it must come from the other house, which is called the Odelsting, or House of Commons. The Lagthing can only deliberate upon what is sent to it, and approve, reject, or send back the bill with proposed amendments. It is also the court before which, aided by the Hoieste Ret Court, an independent branch of the state, the lower house may impeach ministers of state. The Storting consists, in fact, of three houses—the Lagthing, the Odelsting, and the entire Storting. In this latter all motions are made and discussed; and, if entertained, are referred to committees to report upon to the Storting. The report, when received back from a committee, is debated and voted upon; and, if approved, a bill in terms of the report is ordered to be brought into the Odelsting. This house entertains or rejects the proposed bill, frames and discusses the enactments, if it is not rejected *in toto*, and sends it up to the Lagthing or upper house, to be deliberated upon, approved, rejected, or amended. In regard to the passage of bills through these two houses, the practice of the Norwegian Parliament does not differ materially from that of our own, except in the more limited functions of the Lagthing, the king having only a suspensive veto. But if a bill pass through three successive Storthings, it becomes the law of the land without the royal assent. This was exemplified in the case of the bill, already mentioned, for the abolition of hereditary nobility. The duties of the Storting need not be minutely specified; they may easily be inferred. The members are paid for their services; and no executive officer of government can sit in either house. The clearest and most concise account of the constitution of Norway will be found in Mr Forester's *Rambles in Norway*, published in 1850, and in Mr Brace's *Norse-Folk*, published in 1857.

Jurisprudence.

For legal purposes, the whole country is divided into five stifts or provinces, and these are farther subdivided into 17 ams and 64 judicial districts, each of which last comprehends several prestigilds or parishes. To each of these divisions there is a distinct tribunal, with a supreme court of ultimate appeal for the whole kingdom, established at Christiania. The lowest court, which is strictly one of equity, not of law, is the court of mutual reconciliation or agreement held in every parish, and over which presides a commissioner, who is elected every three years by the householders, and holds his court once a month, receiving a small fee. Every case or lawsuit whatsoever must pass through this preliminary court, where no lawyer or attorney is permitted to practise. Each party states his own case; and if by the judgment or advice of the commissioner the parties are brought to agree, his opinion is duly registered in another court held in the parish, and it has all the validity of a final decision. If, however, the litigants are not satisfied, they carry their case to the lowest legal court, that of the sorenskriver, or sworn writer, which is held in every parish of each district once in every quarter. The sorenskriver's court is of great importance. Besides judging civil and criminal matters, it is the court of registration affecting property in the district,

and also of ascertaining the value of, and succession to, the property of deceased persons. The court next above is the stift-amt court, or that of the province, and is thus constituted: It consists of three judges with assessors, is stationary in the chief town of each province, and is the court of appeal from all the lower tribunals of the province, having at the same time the revision of their administration. It must likewise sanction their decision in criminal matters before sentence can be pronounced. There is, lastly, the Hoieste Ret Court of final appeal. It consists of seven judges, and, by the ground law, is one of the three estates of the constitution, being independent of the executive and legislative branches. To this court appeals are carried in the last resort, from the stift-amt courts, in criminal as well as civil cases.

The Norwegian system of jurisprudence presents some remarkable features, not the least important of which is, that the judge is responsible for his legal decision; and in a case of appeal to a higher court, he must there defend his judgment, being liable in damages for a wrong decision. This principle involves a high responsibility, and must occasion some individual annoyance, as well as expense; but it does not prevent able lawyers from becoming candidates for judicial functions; and beyond all doubt it is of great advantage to the public in giving certainty to the law, and in preventing as well as remedying erroneous decisions. The punishment of death was abolished by the Danish government about the latter end of the last century, a measure of questionable expediency in this country, at least where the secondary punishments are by no means perfect. But the punishment which is found the most effective, and which forms one of the most distinguishing characteristics of the country, is that of the "loss of honour." From the earliest times this has been a specific punishment in the criminal law of Norway, standing next in degree to the loss of life. There is, and always has been, much more of the real business of the country in the hands of the people of Norway, and transacted by themselves, than is possessed by the inhabitants of any other European nation. Now, as the "loss of honour" involves exclusion from all the functions which naturally devolve upon them, the punishment is very severely felt, and looked upon, even by the humblest peasant, with the greatest dread.

The Norwegian Church is in principle and doctrine Lutheran, and remains as it was originally moulded after the subversion of the ancient faith, unaltered by the spirit of innovation, and unviolated by the hand of power. It is essentially ceremonial, and has been considered by some almost as much so as the Roman Catholic. Mr Forester, however, justly observes, that such persons look only at the surface of things. "They have been startled," he says, "by the array of images on the altar, the display of rich vestments in the celebration of the eucharist, and the use of the unleavened wafer, together with a high degree of reverence, accompanying the administration of that sacrament; and from these appearances have been led to conclusions which are by no means justified." "It would be more correct to say that the public worship of the Lutheran Church essentially differs from the Roman Catholic, and has a close affinity to that of the Church of England. It is, indeed, ceremonial and liturgical. . . . But there is nothing superstitious in her ceremonial; and her ritual, like our own, contains nothing that is contrary to the Word of God." The altar of the Norwegian Church is decorated with crosses and images, and the priest, arrayed in embroidered robes of velvet, celebrates high mass under that name. There are in Norway 336 prestigilds or parishes, and many of these are exceedingly large, extending in some parts from the sea-coast to the Swedish frontier, and containing from 5000 to 10,000 inhabitants. This is certainly a low provision for religious instruction; but the people, generally

Norway.

Norway. speaking, are scattered all over the country, not clustered in towns and villages; and although individually they are not affluent, they are at least respectable, notwithstanding that as a whole they are poor. Under such circumstances parishes must necessarily be large. There are five bishoprics in Norway, each of which has in it a number of inferior clergy. The patronage is in the hands of the five bishops and the council of state, a committee of which has charge of all the affairs of the church. The incomes of the clergy are derived from tithes, commuted into a payment of grain, glebe farms (one of which the widow has for her life), offerings, and dues. These incomes in country parishes vary from L.150 to L.350; but in large towns or thickly-settled parishes they are higher. The bishops have about L.800 to L.900 each. In proportion to the other professional classes in the country, the clergy are well paid, and the church has always been the first profession to which talent is naturally directed. The clergy are laborious and zealous in the discharge of their duty, the church service forming the smallest part of it. They have school examinations, Sunday schools, and other institutions for the promulgation of Christian knowledge. It is a peculiar characteristic of the Norwegian Church that there is no dissent from it; there are no sectarians in the country. In political rights and privileges the clergy are on a footing with the rest of the inhabitants, and are represented in the Storting like other citizens. One chief cause of the influence of the ministers of religion, and the absence of dissent, is the high consideration in which the right of confirmation is held. The person who has passed this ordeal is regarded as having received a moral as well as a religious diploma, which capacitates him for an office of trust and responsibility.

Education. There are few countries, perhaps, where education has of late years been more attended to than in Norway. In all the large towns there are public schools, and academies and schools for mechanics and artisans. The latter are called drawing-schools, of which there are eight, where mechanics are instructed in modelling, drawing, mathematics, &c. In the diocese of Christiania alone, Mr Brace tells us, that there are no less than 197 stationary schools, besides a high school. In many of the towns there are charity schools, where the children of the poor remain during the day, while their parents are at work. These are supported by public and private contributions. Education is very generally diffused; but great difficulties exist, owing to the population, though not numerous, being so scattered. In the country parishes there are parochial schoolmasters, of whom some have fixed residences, and others live for one-half of the year in one place, and for the other half in another. A small tax is levied from each householder, and every adult pays a small personal fee. There is a considerable degree of intelligence evinced in some of these communities; but the schools are too widely scattered over a thinly-peopled country to be equally beneficial to all. It may be mentioned, that the clergy pay particular attention to the diffusion of education. The higher department of university education at Christiania is expensive; and, besides, there is not such a demand for educated men in the medical, legal, and commercial professions, as in more densely peopled and commercial countries, the tendency of which undoubtedly is to raise the standard of intellectual proficiency amongst all classes of the community. Those belonging to the learned professions are not numerous, because the demand is not great, and the supply is adjusted accordingly. The restrictions on the free exercise of trade and industry also operate with great force in depressing general education. Before a person can enter upon any medical or legal employment, before he can manufacture, buy, or sell as a merchant, he must obtain peculiar privileges from a corporate body. "As the expense of preparation," says Mr Laing, "and the small number of prizes to be obtained, place the

higher and learned professions out of the reach of the main body of the people, as objects of rational ambition, for which they might endeavour to bestow superior education upon their children; so the restrictions and monopoly system shut them out from various paths and employments for which ingenuity, with ordinary useful education, might qualify them."

From the general diffusion of periodical publications, the Norwegians are a reading people. What is of great importance to the community is, that the press is by law perfectly free. There is no duty on newspapers. Every little town has its local newspaper; and from the importance attached to local subjects there discussed, the bulk of the community are the purchasers, not the educated few. In type and paper they are superior to the French or German papers, and much ability is shown in conducting them. There is no scurrility nor personal abuse displayed by those who write in them; yet the most entire freedom of discussion exists, public men and public measures being handled freely but decorously, and with a strict eye to the general good. Several monthly journals are devoted to literature, antiquarian, agricultural, and military subjects; and in almost every newspaper there is the announcement of some new work or translation. Yet the literature which ought strictly to be considered as Norwegian is not yet of a very high order, compared with that of other countries. But the mind of the country is advancing, and literature, which is young in Norway, will advance along with it.

The inhabitants of Norway are very polite in their manners, as well to each other as to strangers. There is a natural *bonhomie* among the peasantry which is very agreeable to meet with; shaking your hand for the smallest benefit conferred upon them, even for the payment of what is their due. They are partial to theatrical representations, so that the drama holds a high place in their estimation; and, besides the public theatres, there are societies of amateur performers in all the larger towns, and even in some of the villages. In music, dancing, and dress, the Norwegian females are by no means deficient. They have pleasing voices, and in every family of every station singing and dancing are constantly practised in the long winter evenings. Music is taught in the country by the organist attached to each parish. In the winter regular fairs are held, at which Swedes and Laplanders attend for disposing of goods. Mr Bayard Taylor tells us, in his *Northern Travels*, that at Raubyen, which is a large village, with a stately church, the people were putting up booths for a fair in Lat. 65. N. in the open air, with the mercury freezing. Christmas is kept in great style, and there are other festivals and various amusements which serve to relieve the tedium of winter and spring. The 17th of May, also, being the anniversary of their independence, is celebrated both at home and abroad by every Norwegian, and with marked propriety. Mr Laing gives a favourable account of the state of morals in Norway; but, without impugning so high an authority, if we are to take bastardy as a test, the statement is not borne out by the facts. The proportion of illegitimate to legitimate children is as 1 to 10; but the evils entailed upon society by illegitimacy are partially alleviated by the state of the law in respect to this. Children are not only rendered legitimate by the subsequent marriage of the parents, as in Scotland, but the father, previously to his contracting a marriage with another party, may, by a particular act, legitimize them. The Norwegians are, at all events, a very hospitable, honest, industrious, peaceable people, and the great mass virtuous in the opinion of all travellers.

Norway is not deficient in her charitable institutions. Mr Brace, in his work entitled *The Norse-Folk, or a Visit to the Homes of Norway and Sweden*, considers Bergen as the most conspicuous town for its institutions of charity. He states, that with a population of 28,000, it appropriates

Norway.
The press.

toms.

Charitable
institu-
tions.

Norway. L.6500 per annum to the poor and sick, besides the sums for public institutions. There are the Old Sailors' Asylum, 120 inmates; the Widows', 31 inmates; the Old Warders', 30; the Old Citizens', 60; Leprous Hospital, 600; Hospital, 120; Insane Asylum, 50 inmates. The mode of disposing of the vagrant and criminal children is similar, says Mr Brace, to that adopted by private organization in his own country (America),—"the sending them to individual homes in the country, where responsible parties are bound to support and educate them. There seems to be a very regular and exact visiting of the poor by public inspectors, who are bound to serve without pay for four years. These report if the children do not attend school, or are vagrant, or falling into criminal habits; they also dispense assistance, and give permits for the different asylums and institutions." At Christiania there is an institution for vagrant and houseless girls, the Eugenia Stift, which, the same author tells us, seems excellently managed; and a new insane asylum, "a large building arranged on the best modern principles. There is no wall about the asylum, and the view is exquisite, enough in itself to be a cure for the diseased mind."

Public
improvements.

The government of Norway, aware of the value and importance of steam navigation, has made great and judicious exertions to promote it. This is a country where it is calculated to produce its greatest benefits, from the manner in which the peninsula is traversed by long arms of the sea, penetrating sometimes to its very centre. Steam-vessels are now seen plying on these fiords, and during the summer months they navigate the whole coast from Christiania to the North Cape. They are commanded by naval officers; the fares are moderate; and in all that regards the comfort of passengers they rival our own. Roads and bridges are kept in a state of excellent order; a circumstance likely to happen in a country of proprietors, whose common interest it is to keep them in repair. There are no tolls in Norway; the principle of the farmers and others is to work in concert, and to keep up establishments for the common benefit. A railway, the only one in Norway, not long since opened, runs from Christiania to Eidsvold, and will be continued to Minde, at the foot of the Miosen Lake, a distance of 50 or 60 miles. A steamboat thence plies to Lillchammer, at the head of the lake, a further distance of about 70 miles, thus opening a direct communication to the sea with one of the most productive parts of the interior. The easiest approach from England to Norway is from Hull, whence there is a weekly steam communication with Christiansand during the summer months; but to those not fond of the sea, the best route is by Calais, and, taking the rail through Hanover, Hamburg, and Kiel, proceed by steamboat to Korsos, and again by rail through Zealand to Copenhagen, whence there are steamers through the Cattagat to Gottenburg and Christiania. Many of our countrymen now visit this delightful country.

The worst feature, perhaps the only thoroughly bad one in the institutions of Norway, is, that the trade is not free. Each trade is monopolized by a sort of guild or fraternity, by which even country dealers are licensed. The pernicious effects of such a system are sufficiently manifest, and we shall close our account of this interesting country with the following observations, extracted from a work of great authority on such subjects:—

"The principle of equal partition of land among all the children, retained in Norway from the earliest period, prevailed also in England before the Conquest. A relic of it remains in the law of gavelkind, still existing in Kent. The different effects produced on society by the retention of that law in the one country, and its general disuse in the other, are remarkable. In Norway, chiefly by its operation, a high standard of sufficiency has been preserved among the middle and labouring classes. Population has been prevented from increasing too rapidly by the fear which people have of falling below the general standard. There has, therefore, been a continual prevalence and diffusion of ease and wellbeing. But on account of the absence of great inequalities of condition, and therefore of many of the usual stimulants to exertion, society has been kept at a low level. Great social freedom has indeed always existed, in consequence of the land being in the hands of the mass of the people; but there has been a want of ability, until a very recent period, to combine for the preservation of their political independence. During their earlier history, their political liberties were often variable and uncertain. After the union of their crown with that of Denmark in 1380, it appears that the Danish nobility gradually encroached upon their privileges; for when, in 1660, the crown and the people combined against the nobility, and abolished the states in Denmark, a similar revolution also took place in Norway; and that country continued under absolute government until the establishment of its constitution in 1814. Their udal laws trained them in the management of their own affairs, and produced that feeling of self-respect which the possession of property, and of land in particular, is calculated to give. These, together with the civil institutions preserved or introduced whilst they were under the Danish crown, prepared them for the large measure of freedom to which they have now attained. The evil of their udal system is its tendency to obstruct the development of intellect, and to keep society stationary. But since 1814 they have made great progress. Stimulants to mental activity are now no longer wanting. Their continual collision with Sweden, the problem of their internal restrictions on trade and commerce, the routine of their government, and the wholesome struggles always arising in a free state, will supply them. Their land will become more productive, by the application of science to its cultivation; their trade will also be expanded." (*Edinb. Review*, No. cxxxi, p. 60.) (J. F. S.) (J—N B—W.)

Norway.

History.

NORWICH, a city of England, and the capital of the county of Norfolk, stands in 52. 42. N. Lat., and 1. 20. E. Long., 108 miles from London.

Modern archaeologists agree in regarding Norwich as the *Venta Icenorum* of the Romans, called *Caer Guntum* by the British, and afterwards *North-wic* (north town) by the Angles, the tribe which peopled *Northfolk* and *Southfolk*. As the capital of the Iceni, it was without doubt an important place long prior to the advent of any of these foreign conquerors, the castle being the royal residence of British kings, and most probably of Boadicea. At a later date it became the metropolis of East Anglia, and we have records of the residence of Uffa, Anna, and other royal personages, at the castle. The original structure, however, fell a sacrifice to the Danes, who completely overran this district, under Sweyn. It was rebuilt by Canute; and again suffering injury, was so entirely renovated, if not wholly rebuilt, at the time of the Norman Conquest, as to pre-

sent no vestiges of any other architectural features than were common to all the Norman edifices. The earthworks of the castle-hill, however, bear traces of early British construction; and utensils that have been dug up bear testimony to the presence of the Romans at some period. The military fortification at Caistor, about three miles distant from the castle, which, until recently, was considered the *Venta Icenorum*, is now pronounced to have been the Roman camp, placed there, as it were, to guard the British settlement at Norwich. In 1049 Norwich was created an earldom by Edward the Confessor. In Domesday Book the city or borough is stated as having 1320 burgesses with their families, 25 parochial churches, and between 800 and 900 acres of land. In the reign of William Rufus, the episcopal see was removed thither from Thetford by Bishop Herbert, who in 1096 laid the first stone of Norwich cathedral. Henry I. granted the city a charter containing the same franchise as the city of London then enjoyed, and the government of the city was then separated from that of the castle, the

Norwich. chief officer being styled *Præpositus*, or Provost. From the time of Henry I. to Edward III., the liberties of the city were often suspended, and gradually enlarged. A colony of Flemish weavers, who had settled at Worstead in the reign of Henry I., first introduced the woollen manufactures; a second colony settled in Norwich in the reign of Edward III., and the city was made a *staple* town for the counties of Norfolk and Suffolk. These causes, combined with the sumptuary laws of Edward III., greatly promoted its commercial prosperity. Grand tournaments were held, at which at various times the kings Henry III., Edward I., and Edward III. and his queen Philippa, were present. Edward the Black Prince was also present at a tournament in 1350. The castle, which had been used as a place of confinement for prisoners under the earls, was, in the fourteenth year of the reign of Edward III., given over entirely to the sheriff of the county, and from that time was used wholly as a county jail. In 1403 the city was separated entirely from the county of Norfolk, under the name of the county and city of Norwich; and the first mayor was elected by the citizens. In 1422 the doctrines of the Reformation made their appearance in Norwich; and several persons were executed as Wickliffites or Lollards. A large chalk-pit on the outskirts of the city is to this day known as "Lollards' Pit," from having been the scene of these persecutions, which continued at intervals until the reign of Edward VI. Among the list of martyrs is the name of Thomas Bilney, who was burned in 1531. In 1549 the city was the scene of an insurrection resembling that of the Jacquerie in France and the Peasants' War in Germany. The facts of this local rebellion were simple enough. The poor objected to the inclosure of certain commons and waste lands in the neighbourhood of Attleborough and Wymondham; fences were thrown down; Robert Kett alias Knight, a tanner, a bold and resolute man, headed the rebels, aided by his brother William, a butcher. Their numbers increased, and, marching towards Norwich, they encamped on Mousehold Heath, took possession of the mansion of the Earl of Surrey, and thence proceeded to lay siege to the city. They held courts of justice under a large tree, called the "Oak of Reformation;" and having augmented their numbers from the citizens to 16,000, and strongly fortified their camp, they summoned the city to surrender. For months they maintained hostilities, and the country round was pillaged and laid waste, until at length they gained an entrance to the city, and bore off the mayor and several of the corporation prisoners to their camp. A strong force was sent down for the defence of the city, under the Marquis of Northampton. A regular engagement was fought at the base of the hill, on St Martin's Palace plain, in which Lord Sheffield, a nobleman engaged in the strife, was slain. The rebels prevailed, and forced the marquis to retire, and on his retreat, plundered and set fire to the city in many parts. The Earl of Warwick, assisted by his son Robert Dudley, Earl of Leicester, was then sent to the relief of the citizens. The city was again stormed by the king's troops, and the rebels forced to retreat, after two days' sharp conflict, during which upwards of 3000 were killed. The insurgents were subdued. About 300 of the ringleaders were executed, and the two Ketts were sent to the Tower of London, and being both convicted of high treason, Robert was executed on the top of Norwich Castle, and William on Wymondham steeple.

Norwich, in common with all Norfolk and Suffolk, took up the cause of the Reformation with a vehemence which causes them to stand alone in the annals of history, and has ever preserved the same spirit of progress and independence amongst the masses, amounting to democratic tendencies and tastes. In Elizabeth's reign the burnings of the Roman Catholics rivalled the flames which had been fed by Protestants in former reigns, and martyrdoms for heresy of doctrine, even among Protestants themselves, were far from being uncommon. In 1578 the queen visited the city in person, and very grand doings celebrated the event. During the Commonwealth the city was put in defence against the royal cause, the castle was fortified for the service of Cromwell, the goods of the bishops and clergy sequestered, the bishop's palace sacked, the cathedral and churches plundered and defaced, and Bishop Hall turned out and driven into retirement. In 1645 the city was divided into presbyteries, and the observance of Christmas-day abolished by command. At the Restoration the city was amongst the earliest to do homage to King Charles. In June 1660 the fee-farm of the city was resigned to him, with a present of £1000 in gold; and in 1663 the charter of the city was renewed and enlarged. In 1671 the king visited the city, and was entertained most hospitably. In 1701 the art of printing, which had been discontinued for many years, was revived, and newspapers began to be printed. Few other events of historical interest have distinguished the city, apart from its progress in manufactures.

Manufac-
tures.

It has been already stated that woollen manufactures were commenced in the city by a colony of Dutch weavers in the reign of Edward III. In the reign of Richard II. they declined; discontent reigned throughout the kingdom; and Norwich shared the general

lot of devastation and plunder at the hands of armed bands, 80,000 in number, under Litester, a dyer. In Elizabeth's reign trade revived, through the invitation given to the Dutch and Walloons, then fleeing from the persecutions of the Duke of Alva. Thirty of these were invited to Norwich, all of them experienced workmen, each to bring with him ten servants, to be maintained at the expense of the Duke of Norfolk. These multiplied, until their numbers exceeded 5000. Soon after the settlement of these strangers new articles of manufacture were introduced, and the admixture of mohair and silk with the wool produced a total change in the quality of the goods. The camlets made to order for the East India Company were annually from 12,000 to 20,000 pieces, until 1833, when the order was transferred to Yorkshire for a cheaper but inferior article. In 1784 the manufacture of cotton was introduced into the city; but the invention of the spinning-jenny, and the facilities possessed by the north, with its coal and iron, for the development of that great power, proved fatal to the progress of cotton manufactures in Norwich. In 1819 a new silk and worsted fabric, called "Norwich crape," was invented, and became so fashionable, that during the Walpole administration (1821) court mourning was ordered entirely to consist of it. Subsequently the chalis superseded this fabric; it was woven in Norwich, but printed in London. The most flourishing period of Norwich manufactures was during the middle of the last century, when fabrics of almost every kind were made. The camlet trade of late has greatly revived, and large quantities are now made for exportation. Fancy goods are also made to a great extent for the American and Australian markets in great variety. Poplins; plain, watered, and figured calico; cashmeres, tamataves, gauzes, crapes, silks, satins, satinettes, lustres, mousseline de laines, velvets, &c., are all now produced in abundance by the Norwich weavers. The numbers engaged in woollen manufactures at the last census were 973; in silk and woollen goods, 3996; flax and hemp, 304; cotton, 178. There are also extensive establishments for dyeing and finishing the goods manufactured. During the past ten years the manufacture of shoes has been very largely carried on. At this time the number of persons employed in the work amounts to 2722 men and 1241 women, besides those wives of shoemakers who frequently earn a good addition to their income by binding. There are 114 curriers, 26 fellmongers, and 30 tanners in the city. Very large manufactures of oil-cake, starch, and mustard have sprung up of late. The premises of one new establishment of the kind covers three acres of ground. Brushes are now being extensively made in the city; and tobacco is manufactured in large quantities for London and other markets.

Norwich.

The city of Norwich is built partly upon a plain on the Principal banks of the River Wensum, a tributary of the Yare, and partly on a gentle acclivity of a hill. The ancient boundary walls, of which few fragments remain, inclosed a space of a mile and a half from N. to S., and a mile and a quarter from E. to W. The modern suburbs have, however, long outgrown these limits. Its chief characteristics are its castle, crowning the summit of a curious sugar-loaf hill, of remote but doubtful origin, in the central part of the city; its noble cathedral; its multitude of churches, nearly all built of flint, some very old, but chiefly of the perpendicular period; its quaint guild-hall, a rare specimen of flint studwork; its spacious market-place, and badly-paved, narrow, winding streets, branching off from open spaces or *plains* of frequent occurrence. The unusually large proportion of ground occupied by gardens has obtained for it from very ancient times the title of "The City in an Orchard." The castle, as before stated, is of Norman architecture, occupying the site of an ancient British fortress. The walls of the *keep* exist entire, but the exterior has been so completely renovated as to present quite a modern appearance. The interior, however, preserves its genuine features of antiquity. The space around on the summit of the hill has been inclosed, and very commodious arrangements been made for the accommodation of prisoners, the whole building having been appropriated as a county jail since the reign of Henry III. The castle-hill or meadow beyond the ditch which surrounds the sugar-loaf hill, occupies a large area, and is used as a cattle and sheep market. The fairs are also held there.

The cathedral is one of the finest specimens of Norman Public architecture existing in the country. The tower is unrivalled for the beauty of its details and proportions. It is

buildings.

Norwich. not well situated, being closely surrounded by buildings and walled-in gardens, among which may be traced vestiges of the old monastic edifice of which the cathedral formed a part. The transepts and west fronts have been restored, but not thereby improved in beauty. The chief entrance on the west is a deep and vaulted portal of pointed architecture, above which is a noble well-proportioned window, recently filled in with stained glass, the design of which is totally out of character with the tracery of the window itself. The nave within is grand and imposing, divided in length by fourteen semicircular arches of great solidity and depth, supported by massive piers, excepting in two instances, where the piers are replaced by cylindrical columns ornamented with spiral mouldings. The triforium is composed of similar arches. The side aisles below are low, and the vaultings plain. The nave and aisles are 72 feet in width, and 204 feet in length. The roof is elaborately decorated with sculptured bosses. Two of the arches of the south aisle of the nave are perpendicular, the vaulting being of the latest florid style, strangely out of harmony with the simplicity of the Norman style which prevails around. This formed the chapel of Bishop Nix, the last Roman Catholic bishop of the diocese, famous for his persecutions of the Protestants in the reign of Mary. The choir, which is 183 feet in length, extends westward considerably beyond the tower, is of unusual length, and imposing in its effect. On each side of the entrance are the stalls of the dean, archdeacon, and prebendaries, all beautifully carved. The transepts have been thrown open to the choir, much increasing the accommodation for sittings, and improving the general effect. The chancel terminates with an apsis, in recesses of which formerly were the stalls of the bishop and clergy. The decorating of both nave and choir is peculiarly beautiful; the lantern of the tower, which rises upon four semicircular arches, supported by four massive piers, is handsome, but disfigured by painted medallions on the ceiling. A curious speculative or oriel, for watching the altar at Easter, remains in the north wall of the chancel. There are only two tombs with statues in the cathedral,—one to Bishop Goldwell, a curious specimen of the style of monumental sculpture in the fifteenth century; another, modern, to the memory of Bishop Bathurst, by Chantrey. Mural monuments are plentiful. Sir William Boleyn, great-grandfather of Queen Elizabeth, is buried on the south side of the choir; the founder, Bishop Herbert de Losinga, lies in the centre of the chancel. The cloisters are situated on the south of the nave, and form one of the largest quadrangles in England, being 174 feet in length on each side. They are in excellent preservation, and elaborately-sculptured bosses ornament the vaulted roofs. At the south-west corner are two lavatories. The cloisters were 133 years in progress of building. The church is dedicated to the Holy Trinity. Several chapels still remain about it; only one, however, is fitted up for use—St Luke's, which is used as the parish church. The bishop's palace is a low rambling structure of mixed dates, the most ancient portion being the cellars, which are groined and vaulted. Some ruins exist of an ancient refectory, now overgrown with ivy. The whole place was thoroughly desecrated and spoiled at the period of the Commonwealth. Two of the gates of the Close are fine specimens of the architecture of the thirteenth and fourteenth centuries.

The next public building of importance is St Andrew's Hall, a fine old ecclesiastical structure, originally the nave of the church of the Black Friars' monastery. At the Reformation and suppression of the religious houses, the corporation of the city negotiated the transfer of this handsome edifice to its possession for the sum of L.80. Since that time its nave has served the purposes of a spacious town-hall, and is used for every variety of civil and political meeting, most especially for the triennial musical festivals

for which Norwich is so justly celebrated. The chancel has always been preserved for religious worship, having been leased by the corporation to the Dutch congregation, who in their turn grant permission for its use to the chaplain and poor of the workhouse, which stands on the site of other parts of the monastery, the cloisters being converted into kitchens, &c. The hall is of perpendicular architecture, and was built by the famous Sir Thomas Erpingham. The roof is open timber, and supported by two rows of slender and graceful pillars, which divide the nave and aisles. It is now adorned with portraits of civic dignitaries and other paintings, among which are two historical pieces by Martin, a native of the city, and a fine full-length portrait of Lord Nelson.

The guildhall, an ancient and curious specimen of flint-work, stands in the north-west corner of the market-place. The assizes for the city are held there, as well as all meetings of the magistrates and council. The council-chamber is a handsome room, fitted up with furniture of the period of Henry VIII., and is an interesting specimen of a court of justice of that period. A glass case incloses a naval trophy in honour of Lord Nelson, being the sword of the Spanish admiral, Xavier Winthuysen, presented by his lordship to the corporation. The original letter accompanying the sword is inclosed in the case.

The market-place is an oblong of very irregular outline. Many gable-ended roofs lingering above the modern shop-fronts, and quaint projecting storeys, give a picturesque and somewhat foreign character to the scene. The market is abundantly supplied with provisions of every kind. Poultry and sausages, the staple product of Norfolk and Norwich, of course abound; and in summer the display of plants and flowers forms a very pretty addition to the view.

Norwich has two large public libraries, in addition to the new free library opened in 1857, which already numbers some thousand volumes, and is much frequented by the class for whom it was designed. A good museum, containing one of the finest collections of birds in the kingdom out of London, occupies the only remaining portion of the ancient palace of the dukes of Norfolk in the city. The museum contains the valuable herbarium of Sir J. E. Smith, the distinguished botanist. It has a spacious corn exchange, where a very extensive business is carried on; and assembly-rooms for miscellaneous purposes. The gaol is a modern structure on the confines of the city. The churches, thirty-six in number, besides the French and Dutch church, are not generally worthy of note, save to the antiquarian. St Peter's Mancroft, the largest, is a handsome structure, measuring 180 feet in length, and 60 in height, with north and south aisles. It has lately been completely restored, and fitted up with open seats. The roof is fine open timber-work, and the organ one of those originally built by Harris. The church contains many curious tombs and monuments. The famous Sir Thomas Browne was buried beneath the chancel of this church. The peal of twelve bells in the tower is said to be unrivalled. The tenor bell weighs 41 cwt. St Andrew's, St Stephen's, and St Michael's Coslany churches are the next in importance. Besides the numerous churches, Norwich has two Roman Catholic chapels, a Jews' synagogue, and between twenty and thirty dissenting places of worship. The city is well supplied with charitable institutions. It has four endowed hospitals for the poor, each possessing very large funds. St Giles, the most important, has an income of nearly L.8000 per annum; while as much as L.10,000 per annum is dispensed in the city through the medium of other charitable institutions. The Norfolk and Norwich Hospital may be classed among the most important of these; it was established in 1772, and contains 105 beds. The number of patients that have been admitted since the opening is 47,072

Norwich
||
Nostradamus.

in-patients, and 37,531 out-patients. From December 1855 to December 1856 the number was—in, 781; out, 721. A public dispensary, eye infirmary, infirmary for sick children (established by Jenny Lind), a Bethel blind asylum, orphans' homes, and many other charitable institutions exist, and several very rich benevolent societies.

The corporate body consists of 16 aldermen and 48 councilmen. The mayor and sheriff are chosen annually from their number. The city has sent two members to Parliament since Edward I. Pop. (1851) 68,195. (s. s. M.)

NORWICH, a town of the United States of North America, state of Connecticut, at the confluence of the rivers Yantic and Shetucket, which join to form the Thames, 13 miles N. of New London, and 40 E.S.E. of Hartford. It is built on the slope of a hill, and has a fine appearance from the river, the streets running in terraces one behind the other. There are here county buildings, a town-hall, eight or nine churches, several schools, and six banks. The water of the rivers supplies moving power to several manufactories, which produce woollen and cotton stuffs, paper, ropes, leather, pottery, &c. The River Thames is navigable up to this place; and Norwich also communicates with the sea by means of a railway on each side of the river. There is daily steam communication between New York and a point 7 miles below Norwich. Pop. (1850) 10,265; (1853) about 11,500.

NORWOOD, a town of England, in the county of Surrey, 6 miles S. of London. It contains two district churches, one of Grecian and the other of Gothic architecture; Wesleyan, Independent, and Baptist places of worship; several schools; almshouses; and a Roman Catholic convent. Among the places of interest are the noble public cemetery, and a pleasure ground called Beulah Spa, which contains a mineral spring. Pop. 3977.

NORWOOD, RICHARD. See DISSERTATION IV., § 4.

NOSSI-BE, or NOS-BEE, an island in the Indian Ocean, in front of the Bay of Passandava, on the N.W. coast of Madagascar; S. Lat. 13. 20., E. Long. 48. 20. It is irregular in outline and surface, and evidently of volcanic formation. The highest summit, which is near the southern extremity, is about 1700 feet above the sea, and is covered with fine timber to the top. The area of the island is about 580 square miles. The land near the sea is well cultivated, and produces rice, maize, potatoes, &c., more than enough for the inhabitants. At several places on the coast excellent anchorage may be obtained. Nossi-Be belongs to the French, being a dependency of the Island of Bourbon. Pop. (1851) 15,178.

NOSTRADAMUS, MICHEL DE, or NOTRE-DAME, a celebrated physician and astrologer, was descended of a noble Provençal family, and born on the 14th of December 1503, at St Remy, in the diocese of Avignon. He studied humanity and philosophy at the college of Avignon, and physic at Montpellier. On the outbreak of the plague in 1525 he set out towards Toulouse, and passed on till he reached Bordeaux. After spending five years on the journey, treating all the patients that came in his way, he returned to Montpellier, and was created doctor of his faculty in 1529. At Agen he contracted an acquaintance with Julius Cæsar Scaliger, which induced him to make some stay in that town. On his return to Provence, he established himself first at Marseilles, and afterwards at Salon, where he became a recluse, and employed his leisure in study. In 1546 he rendered essential service by his medical skill to the inhabitants of Aix, then suffering from a severe visitation of the plague. He had for a long time occasionally followed the trade of a conjurer, and now he began to think himself inspired, nay, miraculously illuminated with a prospect into futurity. As often as he fancied these illuminations discovered to him any future event, he entered it in writing, in enigmatical prose sentences; but revising them

afterwards, he thought the sentences would appear more respectable, and would savour more of a prophetic spirit, if they were expressed in verse. This opinion determined him to throw them all into quatrains, and he afterwards ranged them into *Centuries*. When this was done, he hesitated about making them public, till reflecting that the time of many events which he had foretold was very near at hand, he determined to print them. This he did with a dedication addressed to his son Cæsar, an infant only some months old, in the form of a letter or preface, dated the 1st of March 1555. This edition, which includes seven *Centuries*, was printed by Rigault at Lyons.

Henri II., and his mother Catherine of Medicis, having resolved to see the prophet, he received orders to repair to Paris. He was very graciously received at court; and he returned to Salon loaded with honours and presents. Animated with his success, he augmented his work from three hundred quatrains to a complete milliad, and published it in 1558, with a dedication to the king. That prince having died the next year of a wound which he received at a tournament, the book of the prophet was immediately consulted; and in the 35th quatrain of the first century this unfortunate event was, strange to say, found predicted.

So remarkable a prophecy added greatly to his fame, and he was shortly afterwards honoured with a visit from Emanuel, Duke of Savoy, and the Princess Margaret of France, his consort. From this time Nostradamus found himself overburdened with visitors, and his fame daily increased. Charles IX. presented him with a purse of two hundred crowns, together with a brevet, constituting him his physician in ordinary. But the prophet enjoyed these honours only for the space of sixteen months, having died at Salon on the 2d of July 1566. Besides his *Centuries*, we have the following compositions of Nostradamus:—A treatise *de Fardemens et de Senteurs*, 1552; a Book of singular Receipts, *pour Entretenir la Santé du Corps*, 1556; a piece *des Confitures*, 1557; and a French translation of the Latin of Galen's *Paraphrase*, 1552. In addition to various *Prophecies*, some of which were translated into English during his own time, he published the *Almanac of Nostradamus* in 1559. The eleventh and twelfth *Centuries* of his quatrains were published after his death. It is to these productions that the following pungent distich was applied by Jodelle:—

Nostra damus cum falsa damus, nam fallere nostrum est,
Et cum falsa damus, nil nisi Nostra damus.

NOTARY, in its original signification, was applied to a person (*notarius*) employed to take notes (*notæ*) of trials and other judicial proceedings in the Roman courts. These *notarii* represented in some measure our modern reporters, and, like them, employed symbols of abbreviation, or a species of short-hand, to facilitate the reporting of a speaker's words. This appears from various passages in classical and ancient writers, such as Manlius and Martial. The *notarii* were generally slaves; and, in addition to their ordinary duties, not unfrequently took down a man's will in writing, and were sometimes called upon to attend the prefects in the capacity of transcribers, and attest the acts of spiritual dignities when the empire became Christian. In the fourth century the *notarii* received the name of *exceptores*, and the functionaries corresponding most nearly to the modern notaries were termed *tabelliones*. The business of the latter was to draw up contracts, wills, and other legal instruments. It is impossible to determine when notaries were first known in England. As early as the time of Edward the Confessor we read of charters being executed by notaries for the royal chancellor. The power of admitting notaries to practise seems to have been vested in the Archbishop of Canterbury by the 25 Hen. VIII., c. 21, sec. 4. The term of a notary's apprenticeship, and the manner of his admission to practise, are regulated by the act 41. Geo. III., c.

Notary.

Notation
||
Noto.

79, and amended by the 3 and 4 Will. IV., c. 70, and 6 and 7 Vict., c. 90. The recent statutes, 20 and 21 Vict., cc. 77, 85, for the abolition of the ecclesiastical courts, do not affect the notaries. As appears from countless allusions in our literature, it was customary in former times for notaries to make all kinds of legal instruments. Their occupation is now limited to the attestation of contracts and writings of a mercantile kind, to their authentication in a foreign country, to the protestation of bills of exchange, &c. They also receive and take the affidavits of masters and mariners of ships. The notaries have to pay an annual certificate duty, like attorneys, solicitors, and proctors; and in the stamp act, 44 Geo. 3, c. 98, prohibiting persons not duly qualified from preparing deeds relating to real or personal estate, notaries, as well as attorneys, &c., are excepted, subject to their taking out their annual certificates.

In *Scotland*, before the reign of James III., papal and imperial notaries practised until the third Parliament of that king, held at Edinburgh on 29th November 1469, when an act was passed declaring that notaries should be made by the king. It would appear, however, that for some time afterwards there were in Scotland two kinds of notaries, clerical and legal,—the instruments taken by the latter bearing faith in civil matters. In 1551 an act was passed directing sheriffs to bring or send both kinds of notaries to the lords of Session to be examined; and in a subsequent statute, passed in 1555, it was ordained that no notary, "by whatsoever power he be created," should use the office "except he first present himself to the said lords, showing his creation, and be admitted by them thereto." It does not appear that this statute vested the right of making notaries in the Court of Session; but in 1563 it was by law declared that no person should take on him the office, under the pain of death, unless created by the sovereign's special letters, and thereafter examined and admitted by the lords of Session. Since then the Court of Session have in Scotland exercised full and exclusive authority on the admission of notaries in all legal matters, spiritual and temporal. It is the privilege of notaries to expedite the instruments by which a proprietor is infeft or feudally vested in land, to protest bills, to authenticate copies of writings, and generally to do what is usually done by the notary in England.

NOTATION, the method of expressing numbers or quantities by signs or characters appropriated for that purpose. (See ARITHMETIC and ALGEBRA.)

NOTES, in music, are characters used in writing or printing, to mark the pitch and the duration of the sounds of any musical composition. These characters or signs of notation have varied much at different times. Many alterations of those now generally received have been proposed, but not adopted. *Numerical* and *literal* methods of expressing musical sounds have been repeatedly proposed; but it seems that these are even more complicated than the method in common use. A musical shorthand, constructed of alphabetical letters, was proposed in 1805 in France, but rejected; although in numerous cases of simple melody and harmony it might be very useful in saving space to publishers of books. (As to the notation of music in ancient and modern times, see Padre Martini, Hawkins, and Burney, and especially Mersenne and Mace regarding the *entablature* of some musical instruments now disused.) (G. F. G.)

NOTO, a town of Sicily, capital of a province of the same name, stands on a hill near the left bank of the River Noto, not far from its mouth, and 14 miles S.W. of Syracuse. It is well built, and has regular streets and spacious squares. There are several churches and convents; a college; a museum, with a large collection of Greek, Roman, and Moorish coins; council-house; hospital, &c. Some trade is carried on in corn, wine, and oil. About 4 miles

to the N.W. are the remains of the ancient Netum, consisting principally of an amphitheatre and a gymnasium. Pop. 11,065.

Notting-
ham.

NOTTINGHAM, a large market-town of England, the capital of the county of the same name, in the centre of England. Since the time of Henry VI. the town has been itself a county, with its own recorder and sheriff. It is a place of great antiquity, deriving its name from the Saxon word *Snottingaham*, which is descriptive of its position as a retreat in rocks, since there were formerly many, and are still a few, caverns, cut in the soft rock on which its castle was built. It is by some antiquaries asserted that it was once a Roman station; but that is a subject of controversy. The earliest records notice some incursions of the Danes about 866; but they appear to have received a check from the town, and a defeat near it from King Alfred, who afterwards made it the winter-quarters of his army. William the Conqueror erected a castle, and constructed fortifications so strong as to render the place impregnable against any of the methods of attack which were then known. King Richard Cœur de Lion assembled a Parliament in this place previously to his departure for the Holy Land, and another soon after his return from Palestine. It was from Nottingham that Richard III. marched forth to his fatal battle of Bosworth Field. Here Charles I. erected his royal standard at the commencement of the civil war, at a spot now included in the General Hospital gardens. The castle of Nottingham, defended by the royalists, was besieged by the parliamentary forces under the command of Colonel Hutchinson, to whom, after a brave defence, it at length surrendered. The particulars of the siege are related in a most interesting manner by the wife of that officer. When Cromwell had attained supreme power, he ordered the fortifications to be destroyed, and the castle to be dismantled. Early in the present century this town and neighbourhood were distinguished by the riotous disposition of the lower orders. This was especially the case between the years 1811 and 1814, when the Luddites, as they were termed, were excited to destroy much of that machinery by the aid of which the town subsequently attained to its present high degree of affluence. These disturbances were quelled by the power of the law, and some wholesome severities; but a portion of the trade was transferred to distant and more tranquil districts. During the excitement respecting parliamentary reform a very violent spirit was manifested, which led to the destruction of a silk-mill in the neighbourhood, many outrages upon private houses, and the burning of the castle belonging to the Duke of Newcastle on October 10, 1831. These disturbances led to a few exemplary punishments and some heavy burdens on the town, to indemnify those whose property had suffered by the riots.

Nottingham is finely situated upon the side of a hill overlooking the valley of the Trent, and near to the south-western extremity of what was formerly the forest of Sherwood, once famous as the resort of the celebrated Robin Hood, but now a well-cultivated district. The environs of the town are picturesque and beautiful. It is surrounded, except towards the Trent, by eminences which command extensive views of the neighbourhood and of adjoining counties. Clifton Grove and the village of Wilford, celebrated by Kirke White, together with Wollaton Hall, the seat of Lord Middleton, and Belvoir Castle (distant 19 miles), are marked features in the landscape.

Immediately contiguous to the town, on its western side, is the Park, an appanage of the castle, and originally a grant from the crown. It was purchased of Francis, Earl of Rutland, by William Cavendish, first Duke of Newcastle, who commenced the present building in 1674, in the eighty-third year of his age. The park contains about 120 acres, and is remarkable for its undulatory surface. The boundary next the town is marked by a range of hills upwards of 100

Notting-
ham.

feet high. These terminate abruptly on the south-west with a magnificent precipice, 130 feet high, upon which the castle stands. The whole is of the New Red Sandstone formation, and readily yields to the stroke of the quarryman. It is to the facilities thus afforded by nature that the numerous caverns and rock habitations, for which Nottingham and the Park are so famous, owe their origin. After the estate came into the possession of the present duke, a lofty tunnel was cut through one of the sandstone hills above named, constituting the principal carriage approach from the town to the valley of the Park. The ground is laid out for villa residences, and terraces and drives are formed; the valley being set apart for pleasure-grounds and ornamental planting. The landscape is rarely equalled in beauty, and affords a sudden and magical transition from town to country. Of this the merchants and principal inhabitants have availed themselves, by erecting residences of a costly, and for the most part elegant and tasteful character. The Park is bounded on the south by the River Leen, or rather the artificial watercourse said to be formed by William Peverill, the first grantee of the castle, in the time of William the Conqueror. The original bed of the river as it ran into the Trent may be now traced at the point at which it was diverted.

Some of the old streets are narrow, but in the great extension of the town of late years some new and spacious avenues have been built, and much improvement has been judiciously effected. The market-place is one of the finest in England. It is spacious, occupying an area of 27,515 square yards, or rather more than five acres and a half. It is well paved, and admirably adapted for the purpose of the two weekly markets held in it on Wednesday and Saturday, the last of which is the principal one. At the east of the market-place stands the Exchange Hall, which is a noble-looking building. The pediment is crowned with a well-proportioned pedestal, on which stands the figure of Justice. On the pediment are the town arms; and underneath it, with a clock intervening, is a handsome Venetian window, ornamented with two elegant Ionic columns, which lights the spacious room within. That apartment, when the temporary doors which divide it are thrown open, is 123 feet long, 30 wide, and 30 high, with an arched ceiling. It is used for public dinners, at which more than 400 persons can be commodiously seated, and also for public meetings. This room was nearly destroyed by an accidental fire in 1836, but has been restored and further beautified. One part of the building is appropriated to magisterial business, and another is occupied as a police-office, and for the residence of the mayor's serjeant-at-mace. Underneath the Exchange there are a few shops in front, but the principal part of the ground-floor is appropriated to shambles. In another part of the market-place is the Subscription Library, containing more than 13,500 volumes, many of them of great value. With this is incorporated the Standfast Library, consisting of works chiefly classical and theological; making a total of nearly 15,000 volumes. There are also maps, and portraits of eminent individuals connected with the town, amongst whom are Colonel Hutchinson, Lord Byron, Sir Richard Arkwright, Kirke White, and others.

The other civic buildings are the county jail and hall, a commodious but not elegant structure; the house of correction and town jail, standing on the site of a convent of the hospitaliers of St John of Jerusalem; the town-hall, where the borough assizes and sessions, and the mayor's and sheriff's courts are held; the post-office, occupying a very commanding situation; and the free grammar school, in which 80 boys are educated—40 in the classical, and 40 in the English department.

The edifices for religious worship are in about the same proportion to the number of the inhabitants as is seen in other places which have increased with similar rapidity.

VOL. XVI.

Notting-
ham.

St Mary's is usually denominated the mother church of the town, from its priority of erection. It resembles a cathedral more than a parish church in its extent, its architecture, and its decorations, and is the most striking object in the place when viewed from what is called the High Pavement. It stands on an elevated spot, and is said to be nearly 70 feet above the level of the meadows near the town. The date of the erection is unknown, but is said to have been in the fifteenth century. It is in the form of a cross, and has a handsome square tower, in which there is a musical peal of ten bells. The length of the structure in the inside is 216 feet, the breadth at the transept 97, at the west end or principal entrance 67, and in the chancel 29 feet. The height of the tower is 126 feet, and that of the side aisles 60 feet. The porch on the south side is a very ancient and elaborate piece of workmanship, which tradition has assigned to the neighbouring priory of Lenton as its original site. In the north transept there is an excellent organ of great power. There are in this church many monumental inscriptions on tombs of the family of the Earls of Clare, and one of an Earl of Meath, and the mausoleum of the family of the Wrights. In the year 1848 the building, having undergone extensive repairs and numerous alterations, with a view to carrying out its original design, was re-opened for public worship. The cost, upwards of L.9000, was defrayed by a subscription.

Besides the mother church, there are provided for the adherents of the established worship the following edifices:—St Peter's, St Nicholas', St James's, St Paul's, Trinity, St John Baptist's, St Matthew's, and St Mark's. The Roman Catholics possess a cathedral dedicated to St Barnabas, and erected in 1844 at a cost of L.20,000. The Nonconformists have numerous places of worship, some of them large and costly. Wesley and Halifax Place chapels, belonging to the Methodists, will accommodate each 1800 persons, and the former is stated to have cost L.10,000. Other descriptions of Methodists have 5 places of worship; the Baptists of various orders 7; the Independents 4; the Unitarians, Quakers, Irvingites, and numerous other sects, 1 each. In 1851 the total number of places of worship was reported as 37, of which 8 belonged to the Church of England, and 29 to other religious bodies. The largest reported attendance (on Sunday, March 31) in that year was, at the several churches, 5570, and at the other places of worship 11,284.

The charitable institutions depending on endowed foundations or on voluntary contributions are numerous. The Blue-Coat School clothes and educates about 50 boys and 20 girls. The General Hospital, built in 1781, possesses about two acres of land, given partly by the Duke of Newcastle and partly by the corporation. It is supported chiefly by subscriptions, and usually contains about 140 patients; whilst between 1100 and 1200 are out-patients receiving medical advice and assistance. The Dispensary, established in 1831, has on an average 350 patients. The General Lunatic Asylum is a modern and spacious brick building, erected in 1810, at an expense of nearly L.20,000. There are extensive courts, gardens, and places for recreation; and the whole economy of the place is well contrived for the recovery of the inmates. The foundation of a second asylum for patients of the middle class was laid by the Duke of Newcastle, October 30, 1857. Labray's and Lambley's Hospitals are small asylums for aged widows; and Collins' Hospital is a splendid charity, founded by one of the Smith family of the town, of which Lord Carrington is the present head. It consists of twenty-four small but convenient dwellings for as many poor widows, each of whom receives four shillings weekly, and two tons and a half of coal every year. From the same endowment Carrington Street Hospital, which accommodates 20 inmates, was built between the years 1831 and 1834. Plumptre Hospital, founded by a family of that name (since transplanted into

2 U

Notting-
ham.

Kent) in the year 1392, but twice repaired since,—viz., in 1650 and 1751,—has been rebuilt under an act of Parliament passed in 1823. Thirteen aged widows are provided with comfortable dwellings within the house, and allowed six shillings weekly, whilst thirty others, called out-pensioners, receive ten pounds a year. Willoughby's Hospital contains nineteen tenements, the inhabitants of which receive a small pension. Wooley's Alms are dwellings for six poor persons; and Bilby's Almshouses for eight persons, who have each a loaf weekly, and two tons of coal at Christmas. Warser Gate Hospital gives apartments to six, and Hanley's to twelve poor persons. Other almshouses exist; so that in the year 1844 the number of persons thus provided for was 180. In 1852 Mr George Gill erected six additional tenements for decayed workmen.

Among the public edifices that deserve notice may be mentioned the barracks, built in 1792, a plain building, with apartments for officers and privates, and suitable stabling for three troops of horse. At the close of 1857 the government resolved on erecting new barracks on a different site, granted by the corporation. There is an assembly-room, as well as a theatre of moderate dimensions, and the usual provision of gas and water works, &c. Among the comparatively recent buildings of a public character are a savings-bank; a mechanic's institution, with a hall capable of accommodating 1000 persons, a library of 6000 volumes, a museum of natural history, reading-rooms, &c.; the Artizan's Library, containing 2000 volumes; the People's College, founded by Mr George Gill in 1847, intended to bring the higher advantages of education within common reach; a large and handsome asylum for the blind; a ragged school; a female refuge; and baths and wash-houses. Two of the older mansions of the town are now occupied, the one as a government school of design, and the other as a people's hall, a gift to the working-classes by a benefactor whom we have already named, Mr George Gill. To these must be added a large and handsome building, erected in 1853 as a corn market, and now used as a general exchange and news-room. To this is attached a telegraph office.

The most important event in the modern history of Nottingham was the passing, on June 30, 1845, of an act for the inclosure of about 1300 acres of pasture land, by which the town was nearly encircled, and which was subject to rights of common. Surrounded by this belt of open country, the town had been hemmed in upon a space of 265 acres, and was one of the most densely peopled in the kingdom,—an immense surplus both of trade and population, properly identified with Nottingham, being located in large manufacturing villages in the immediate vicinity. The effects of the act are strikingly apparent. Many hundreds of houses, with numerous factories, now spread over the recently-inclosed space. It is traversed by public and private roads of more than 18 miles in length. Upwards of 50 acres are laid out, for the purposes of public recreation, in a cricket-ground, ornamental walks, and an arboretum of about 20 acres, to which there is free admission. An extensive race-ground is included in the space reserved for public accommodation. The inclosure act also provided for the appropriation of 8 acres for the purposes of interment. Of these, four, designed for the use of dissenters, were added to the general cemetery, established in 1837, and now comprising 18 acres; and the remainder are incorporated with a recently formed Church of England cemetery, containing in all 13 acres.

The change in the town itself is as great as that which marks its immediate vicinity. Factories and warehouses have sprung up with a rapidity of which scarcely any other town presents an example. Almost all the leading merchants and manufacturers have enlarged or rebuilt the places in which they carry on their business; so that Nottingham appears like a place which has suddenly become the seat of some new and very flourishing trade. The old

warehouses, &c., were of the plainest character, and utterly destitute of architectural pretensions. The reverse may be said of the new. Under the direction of Mr Hine and other able architects, the town has now been ornamented with a large number of commercial buildings, which for their architectural character will bear comparison with the higher class of civic edifices to be found elsewhere.

The population of Nottingham amounted in 1811 to 34,253; in 1831 it was 50,680; and in 1841, 53,091. It had grown in 1851 to 58,529, exclusive of the suburbs of Sneinton and Radford, which are now strictly incorporated with Nottingham, and constitute one town. Of these, the former contained at the last census 8840 inhabitants, and the latter 12,637; making a total of 80,006. To these ought perhaps to be added the immediately contiguous parish of Lenton, having a population of 5589. On this estimate, the population of Nottingham, taking into account its rapid increase during the last few years, cannot fall far short of 100,000. The villages within 4 miles, and most of them, strictly speaking, dependencies of the town, contain an additional population of 30,000.

The Trent is navigable up to the town; and the various canals which branch from that river afford the means of communication with every part of the kingdom. There are two distinct lines of railway connecting Nottingham with the metropolis, as well as with the north, besides lines running to Derby, Newark, Lincoln, Mansfield, Ilkeston, and other places.

We are enabled, on the authority of W. Felkin, Esq., F.L.S., to present the following account of the two principal branches of the trade of this important town:—

The surprising invention of the stocking-frame by Lee has issued in one of the most interesting chapters in the history of mechanical invention and manufacturing industry. It was upon this machine that, about a century ago, a coarse imitation of cotton lace was first produced. The fabric was all weft from one continuous thread. A beautiful adaptation of the machinery enabled a fine silk net (point lace) to be made, employing for many years 1500 frames in Nottingham and its vicinity. This fabrication has long since died out. Then the machine was so arranged as that the material should be used altogether as warp. This very ingenious machine is still usefully and extensively employed. Mr John Heathcoat, then a working-frame smith in Nottingham, invented the bobbin-net machine, and patented it in 1809. His first machines were from 18 to 36 inches in width. A woman making lace on a pillow may produce three to five meshes or interstices in a minute. The first machine produced 1000 meshes per minute. A square yard of the produce was sold for L.5. This machine, as originally constructed, though displaying wonderful mechanical skill, was a complicated one. During the whole of the intervening time incessant and remarkable ingenuity has been shown in simplifying and improving the machine. It is now made 180 to 200 inches in width; and plain net of like quality to that first made is sold currently at 6d. for the square yard. A man turns off with ease 40,000 meshes per minute from this "mechanical pillow," as the bobbin-net machine was originally called by its talented inventor. Iuddites having broken the patentee's machinery at Loughborough, he established himself at Tiverton, where he now employs 300 machines. He has represented that borough in Parliament since 1831. There are also about 100 machines at Barnstaple, 250 at Chard, 100 in the Isle of Wight, and 300 in Derbyshire. There are 2550 bobbin-net and 800 warp machines at work in Nottingham and its vicinity. Excepting less than one-tenth of the production, the whole of the English bobbin-net machinery is employed for the Nottingham lace trade. The capital in this machinery amounts to L.1,500,000, independently of that employed in the construction of doubling and throwing raw materials used in this branch of business. The number of persons wholly or in part engaged in it is 135,000, or more—as smiths, machine hands, menders, warehouse men and women, finishers, embroiderers, &c. Wages may be stated at,—men 20s. to L.5; youths, of both sexes, 8s. to 20s.; children, 3s. to 8s. per week. The whole machinery, or nearly so, is worked by steam or water power, where employed on plain or common fancy goods. The Jacquard apparatus has been applied at great cost, but with perfect success, to about 2500 of the machines, making every class of bobbin-net and warp goods, up to the most expensive and close imitation of pillow articles. The statistics for 1857 may be stated, with pretty close approximation to truth, as follows:—

Notting-
ham.

Nottingham.

Nottinghamshire.

3600 bobbin-net, and 800 warp lace machines used up 9,600,000 lb. weight of raw cotton wool, at an imported cost of £712,000, to which was added £2,318,000 wages and profits; making a total return of £3,030,000: and raw silk, 450,000 lb., at a cost of £503,000, to which was added wages and profits £1,247,000—total return in silk lace goods, £1,750,000. There were therefore materials used costing £1,215,000, to which were added wages and profits £3,565,000; making the entire return £4,780,000, of which £4,300,000 passed through the warehouses of Nottingham. About two-fifths of the amount is believed to be exported. During the first twenty years after the bobbin-net machine was invented, pillow lace was very adversely affected by it. Since then the cheaper machine lace has led the way to a larger consumption of pillow lace goods, and at better wages and prices than for ages before.

Hosiery trade of Nottingham in 1857.

The machinery invented in 1589 by the Rev. W. Lee, at Woodborough, in the county of Nottingham, for the manufacture of hosiery, was the result of extraordinary mechanical genius. After his death it was chiefly transferred to and around London; but a century ago it had become concentrated in the three midland counties. In order to bring before the public the sufferings of the people then engaged in this branch of trade, Mr William Felkin of Nottingham caused a minute census of the machinery to be taken in 1844. This statement included the frames, hands employed, classes of work produced, materials used, throughout 230 parishes in the counties of Leicester, Derby, and Nottingham, where stocking-frames were to be found, as well as those which were in other parts of the three kingdoms. In Leicestershire there were 6933 employed upon cotton, 9875 woollen, 168 silk, 1582 mixed, and 2303 not at work; total, 20,861. In Derbyshire, 4380 cotton, 171 mixed, 1454 silk, and 792 not at work; total, 6797. In Nottinghamshire, 12,440 cotton, 2094 silk, 299 mixed, 46 woollen, and 1503 not at work; total, 16,382. In other parts of England, 1572 frames; in Scotland, 2605; in Ireland, 265. Total stocking-frames in the three kingdoms, 48,482.

These machines had been worked in small shops, or the houses of work-people. The rates of wages in 1844, and for forty years previously, had been depressed to the lowest living point, it being all hand employment. Since that year there has been a gradual but most important improvement throughout the whole trade. The demand for goods has gone somewhat beyond the supply of labour; the rates of wages have advanced 50 to 100 per cent., according to classes of goods made; all the available machinery has been employed, though the former excessive hours of work have been shortened; and the former wretchedness of the people has disappeared. During the last ten years about 1300 sets of power rotary round frames have been constructed, about 800 of which are in Nottingham, and 500 in the two adjoining counties. Several hundreds of wide frames have been placed in factories, and adapted to rotary steam-power. Out of the total number of stocking-frames (about 50,000), there are now at least 17,250 engaged in the trade of Nottinghamshire, giving employment in making, stitching, sewing, finishing, &c., to about 40,000 men, women, and children, at from 30s. to 2s. 6d. a week. Of the production of Nottingham hosiery, about one-third, it is believed, has been of late exported. The value of Nottingham hose-frames is estimated at £310,000.

The kind and quantity of materials used, and value of hosiery goods produced in 1857, bear no comparison with 1844, or any former period. One workman in a hand-frame may produce one dozen cotton hose, weighing 2 lb. on an average, in a week; one set of round frames, managed by one man, will turn off easily 200 dozen, each of 1½ lb. weight (using 300 lb. of cotton per set) in a week. Such hose are selling, when prepared for market, at 2s. 6d. per dozen. This cheap hosiery has forced its way where stockings were unknown; and in both home and foreign markets an increased demand for every class of English hosiery has marked the late epochs of enlarged manufacturing prosperity.

The following is an approximate estimate of the production of hosiery in the Nottingham trade of the year 1857:—

Material.	Consumpt of raw material.	Cost in Import.	Wages and Profits.	Total Return.
	Lbs.	£.	£.	£.
Raw cotton wool..	9,000,000	338,000	987,000	1,325,000
Mixed wool.....	2,600,000	107,000	333,000	440,000
Raw silk	100,000	100,000	235,000	335,000
Total	545,000	1,555,000	2,100,000

Nottingham has been celebrated for its ale, the qualities of which have been the theme of song. It is still good, and very potent. Its excellence has been attributed by some to the good quality of the barley grown in the neighbourhood, by others to the purity of the water, and by many to

the excellent cellars scooped out of the rock, with which most of the good houses are furnished.

This town returns two members to the House of Commons. The freemen, who were formerly the sole electors, are still numerous, but are exceeded in number by the ten-pound voters.

By the municipal corporation reform law passed in 1835, the town is to continue a corporation, is divided into seven wards, and has a mayor, fourteen aldermen, and forty-two councillors, with twelve justices of the peace appointed by the crown. (S. M.—LL.)

NOTTINGHAMSHIRE, an inland county of England, bounded on the N. by Yorkshire and a part of Lincolnshire, on the E. by Lincolnshire, on the S. by Leicestershire, and on the W. by Derbyshire. It is of an oval figure, with its narrowest end towards the north. Its greatest length is about 50 miles, and its greatest breadth 27. Its circumference is estimated at 140 miles. The number of square miles is 822, or 526,076 acres.

The county is divided into six hundreds, or, as they are usually denominated, wapentakes; three of which are to the north and three to the south of the River Trent. It contains nine market-towns, and 207 parishes. The annual value of the real property assessed to the property and income tax for the year ending 5th April 1851 was £1,198,843. The number of inhabitants amounted in 1801 to 140,350; in 1811 to 162,000; in 1821 to 186,873; in 1831 to 225,400; in 1841 to 249,910; and in 1851 to 270,427.

The number of inhabited houses in 1851 was 55,019. We are not enabled to state the exact proportions of the several classes engaged at that date in trade, agriculture, &c. According to the census of 1851, the county contains 231 public day-schools, 58 of which are supported by endowments, and 136 by the voluntary subscriptions of members of the Established Church. The total number of scholars in public and private day-schools is 31,178. The number of Sunday-schools is 428, of which 183 belong to the Established Church, and 245 to other religious communions. The total number of scholars in the former is stated to be 17,785, and in the latter 26,153. The places of worship belonging to the Church of England are returned as being 248, and those belonging to other religious bodies as 382, of which the large proportion of 273 is assigned to the Wesleyan Methodists. The number of sittings is reported as 160,234, of which the Established Church furnishes 76,960.

The towns and villages containing more than 2000 inhabitants, and the numbers in each, were in 1851:—

Nottingham	58,529	Southwell	3,516
Newark	11,330	Beeston	3,016
Mansfield	10,627	Hucknall-Torkard	2,970
Basford (parish)	10,093	Retford	2,943
Workshop	7,215	Clarlborough	2,504
Sutton in Ashfield	6,542	Kirby in Ashfield	2,363
Lenton (parish)	5,589	Carlton	2,329
Greasley (parish)	5,284	Ruddington	2,181
Arnold	4,704	Bingham	2,054
Bulwell	3,786		

The face of the country is generally level, with moderate undulations; and its beauties are of a mild description, somewhat picturesque in the vicinity of Sherwood Forest, but displaying neither the striking features of the adjoining county of Derby on its western side, nor the flat insipidity of the plains of Lincolnshire on its eastern side. From its position between these two descriptions of country, and from its moderate elevation, it enjoys a milder climate than either, partaking neither of the cold air of the one nor the moist atmosphere of the other. The mean temperature of the county town is said to be only 1½° below that of London, or 49°-73. The dryness of the climate is favourable to early vegetation, and is supposed to be the cause of the seed-time and harvest in Nottinghamshire commencing at the same period as in the more southern counties.

Nottinghamshire.

The soil of this county is very various. On the borders of Derbyshire there is a stripe of land with coal and limestone, partly in wood, but mostly under arable culture. Parallel to it is a broader tract, including Sherwood Forest, the soil of which is chiefly sandy and gravelly; but though naturally sterile, it has in some degree been brought into a productive state by the extensive cultivation of turnips, and the maintenance of considerable flocks of sheep. The tract which adjoins is a clayey soil, extending to the banks of the River Trent. It is chiefly arable land, but varied with woods and meadows, and highly productive of wheat, oats, beans, and, in some parts, of hops. The lands on the banks of the Trent are very fertile, being mostly devoted to pasture, on which many oxen are fattened; and some of the dairies are extensive. The arable land of this district is celebrated both for the quantity and the quality of the oats which it produces. The beautiful vale of Belvoir, in the south-easternmost part of the county, enjoys some of the best soils, both for pasture and arable husbandry, of any part of this island. The farms are in general small, and commonly held by tenants at will, the rents taken from whom are generally moderate; and a very great proportion of the land is free from the burden of the tithes. The spirit of agricultural improvement has not proceeded so far as in many other counties, though it has made considerable progress of late years. Neither the breeds of cows and sheep nor the modes of cultivation differ so much from those of the adjoining counties as to deserve any especial notice.

There are no mines except those of coal, which are exclusively confined to a narrow district bordering on Derbyshire; the coal is of good quality, very abundant, and, by means of railways and internal navigation, diffused throughout the whole county. Excellent stone for building is raised in many parts, some of which has the peculiarly valuable quality of hardening by exposure to the weather. Many parts of the county abound in veins of gypsum. In the parish of Gotham it is found in strata of the thickness of 3 feet. At Beaconhill, near Newark, there are large quarries of this substance. Although it has been much praised as a manure, the trials of it that have been made in its vicinity have not been attended with such beneficial results as to induce the continued use of it for that purpose. It should only be used in moderate quantity, and on stiff soils.

The forest of Sherwood, formerly celebrated as the scene of the exploits of Robin Hood, whose deeds amused our nursery days, is mostly an open heathy plain, bordered with recent plantations, and upon which the plough has made very extensive encroachments. The boundaries of the forest are extensive, it being 25 miles in length, and from 7 to 9 in breadth; but a great portion of it has become the property of private individuals, and is inclosed in farms and parks; in the latter of which is to be found the deer with which this forest was once most abundantly stocked. The trees of most ancient date are those on the estates of the Duke of Newcastle and Lord Manvers.

Nottinghamshire is, for its population, one of the greatest manufacturing counties. (For information on this subject the reader is referred to the concluding part of the article NOTTINGHAM.) The spinning of cotton-yarn, from its natural connection with the trade of the district, has been introduced and very widely extended; and the establishments at Nottingham, at Pleasley Works, near Mansfield, and several other places, are upon an extensive scale. There are also some large manufactories for silk-throwing and for spinning worsted yarn. Malting and brewing are carried on to a considerable extent; and the beer of Nottingham and of Newark rivals that of Burton-upon-Trent. There are potteries at Sutton-in-Ashfield; starch is made at Lenton; and sailcloth and candlewick at Retford.

The foreign trade of this county is mostly conducted by the mercantile houses of London and Liverpool; but some

of the larger manufacturers export their own goods both to the continent of Europe and to the more distant parts of the world.

Nottinghamshire.

The River Trent, the fourth in magnitude of the English streams, passes across the county, and is navigable for barges throughout the whole of it; but its deficiencies of water and its shoals are such great impediments that a canal by the side of it, 10 miles in length, is found of great use to the intercourse. The other rivers are not navigable, but are beneficial for the purposes of irrigation. They are the Erewash, the Soar, the Maun, the Meden, the Wollen, the Worksop, the Idle, the Leen, and the Dover or Dare. These all discharge their waters into the Trent. The canals are—the Nottingham, the Grantham, the Idle, and the Chesterfield. The last of these is about 40 miles in length; the others about 10 each. By means of these and the Trent, the intercourse by internal navigation is extended to almost every district of the county. In addition to this means of communication, all the principal towns, and most of the more populous villages, are now embraced in the railway system.

The titles derived from this county are those of Marquis of Granby, Earl of Mansfield, Viscount Newark, and Barons Pierrepont and Carrington. For election purposes, the county has been divided into two districts, the northern and the southern. Each of them returns two members. The election for the northern division is held at Mansfield, and the polling-places are, that town, East Retford, and Nottingham. The election for the southern division is held at Newark, and the other polling-places are Bingham and Southwell. The three boroughs, Nottingham, Newark, and Retford, return each two members, as before the passing of the Reform Bill. The whole of the county is in the diocese of Lincoln, to which it was transferred from that of York at the recommendation of the ecclesiastical commissioners in 1836. It is on the midland circuit of the judges.

The remains of Roman and Norman antiquities are numerous. Amongst the former are the camps at Barton Hill, at Combes Farm, at Gringley, at Hexgrave, and at Wenney Hill, and a Roman villa near Mansfield. Among the latter are the Castle of Newark; the abbey of Newstead, Rufford, and Welbeck; the priories of Mattersey and Worksop; and the churches of Bingham, Blythe, Southwell, and Balderton.

Among the distinguished natives of this county have been Archbishop Cranmer, Dr Erasmus Darwin, Sir Martin Frobisher, Denzil Lord Holles, Ireton, the son-in-law of Cromwell, Lady Mary Wortley Montague, Paul Sandby, Archbishop Secker, Gilbert Wakefield, Bishop Warburton, and Henry Kirke White.

The seats of noblemen and gentlemen of the first class are as numerous as in any county of England. Among the most remarkable are the following, viz.:—Annesley Hall, John Musters, Esq.; Babworth Hall, H. B. Simpson, Esq.; Bramcote Hall, J. S. Sherwin, Esq.; Bunny Park, G. A. Forteath, Esq.; Clifton Grove, Sir Robert J. Clifton; Clumber Park, Duke of Newcastle; Colwick Hall (unoccupied); Elton Manor, W. F. N. Norton, Esq.; Flintham Hall, T. B. T. Hildyard, Esq.; Grove Hall, G. H. Vernon, Esq.; Holme Pierrepont, Viscount Newark, M.P.; Kelham House, J. H. M. Sutton, Esq.; Kingston Hall, Lord Belper; Mapperley House, Ichabod Wright, Esq.; Newstead Abbey, late Lord Byron (now Colonel Wildman); Norwood Park, Sir John Sutton, Bart.; Nuttall Temple, R. Holden, Esq.; Osberton, George S. Foljambe, Esq.; Ossington Hall, Right Honourable J. E. Denison, M.P.; Oxtown Grange, H. P. Sherbrooke, Esq.; Ruddington Grange, Charles Paget, Esq., M.P.; Rempstone Hall, Lady Sitwell; Rufford Abbey, Earl of Scarborough; Serlby Hall, Viscount Galway, M.P.; Stanford Hall, Rev. S. V. Dashwood; Thoresby Park, Earl Manvers; Thrumph-

Noureddin. ton Hall, Honourable Captain Byron; Thurgarton Priory, Richard Milward, Esq.; Watnall Hall, Colonel Rolleston; Welbeck Abbey, Duke of Portland; Whatton Manor, T. D. Dickenson, Esq.; and Wollaton Hall, Lord Middleton. (S. M.-LL.)

NOUREDDIN, or NOOR-ED-DEEN, the name of several Moslem rulers of Syria, of whom the most distinguished was NOUREDDIN MAHMOUD, *Melek-El-Adel*, who succeeded his father the famous Zenghi, Emir of Aleppo, in 1146. His reign was endangered at its commencement by the attempts of the Christians to regain the possessions which had lately been wrested from them. Josceline de Courtenay siezed upon his former capital Edessa: but he was speedily dislodged, and the rebellious spirit of the citizens was suppressed by an extensive massacre. The second crusade, under the command of Louis VII. of France and the Emperor Conrad, arrived in 1148. But the ranks of the Christian invaders had been wasted in their march by the shafts and scimitars of the infidels; their strength was now still further weakened by the dissensions of the royal leaders; and after sitting down for some time before Damascus, they returned ignominiously to Europe. It was about this time that Noureddin conceived the grand project of rearing an effectual barrier against future crusades by annihilating the dominion of the Christians in Palestine, and uniting all Syria and the neighbouring districts under one government. For achieving such an enterprise his character peculiarly qualified him. His pious zeal had raised him high in the estimation of his fellow-Moslems; his conscientious frugality specially adapted him for the management of military expeditions; on account of his majestic bearing and simple soldier-like manners, he had become the darling of his army; and for his just rule and merciful care for the poor and the oppressed, he was regarded as the father of his people. Accordingly, he began the enterprise with great vigour and success. Raymond, Prince of Antioch, was defeated and slain in 1149; Josceline de Courtenay, Count of Edessa, was taken captive soon afterwards; and the whole of Northern Syria became in consequence the possession of Noureddin. He then turned his attention to the gaining of Damascus. The course of events rendered force in this case unnecessary. Anar, the able vizier of that kingdom, died; the ruler Modjir-Ed-Deen was considered too imbecile to resist the threatened attack of Baldwin III., King of Jerusalem; and in 1154 the terrified inhabitants of Damascus willingly put themselves under the jurisdiction of the powerful and benign Emir of Aleppo. Noureddin had now extended his dominions around the borders of the Latin territories in Palestine, and had thus gained a favourable position for carrying out still further the great project of his reign. A severe illness, indeed, in 1159, and a defeat which the Christians inflicted upon him, gave a check to his success. But speedily recovering himself, he encountered the famous Reginald de Chatillon, prince of Antioch, defeated him, and took him prisoner. Taking advantage also of the distracted state into which the khaliphate of Egypt had been plunged by the contention for the viziership between two emirs, Shawir and Ed-Dirgham, he resolved to extend his influence into that country. Sheerkoooh, and his nephew Salah-Ed-Deen or Saladin, were accordingly despatched at the head of an army to raise the former of the rivals to the contested office. At first the enterprise was unsuccessful. Shawir, after he had been placed in the viziership, refused to fulfil his obligations to Sheerkoooh, and summoned in the aid of Amaury, the son and successor of Baldwin III. The troops of Aleppo were besieged in Pelusium, and were forced to capitulate to the Christians. At length, however, the tactics of Noureddin himself retrieved the declining fortunes of the Moslems. His inroad into the state of Antioch recalled Amaury to its defence; the Christian troops immediately on their arrival

were routed near Tiresia with disastrous loss; and Sheerkoooh being sent once more into Egypt, succeeded, in 1168, in removing the perfidious Shawir by death, and in establishing himself as lieutenant of Egypt in the name of his master. The schismatic khaliphate of the Fatimites in that country was then abolished; the Egyptians were restored to the spiritual jurisdiction of the Abasside khaliph of Baghdad; and that chief of the Faithful conferred upon his meritorious servant Noureddin the title of Sultan, and the direct investiture of Egypt and Syria. Noureddin might now have turned his vastly increased resources against the Latin states in Palestine, and might thus have achieved the magnificent result to which all his past successes had been tending. But the last few years of his life were molested by the ambitious intrigues of the able Salah-Ed-Deen, who had succeeded his uncle Sheerkoooh in the lieutenantancy of Egypt. He was on the eve of setting out to chastise his rebellious subject, when an attack of quinsey brought his days to a close at Damascus in May 1173.

NOVALIS, the literary pseudonym usually applied to FRIEDRICH LUDWIG VON HARDENBERG, a distinguished philosopher and poet of Germany, who was born at a country house of his family in the county of Mannsfeld, in Saxony, on the 2d of May 1772. His father, a frank, rugged, honest German, had spent his early years as a soldier, but was at this time director of the Saxon salt-works. The mother of Novalis was "a pattern of noble piety and Christian mildness," and her son seems to have loved her with the most enthusiastic affection. From both his parents, who were attached to the Herrnhut communion, Novalis inherited that decidedly religious temper which continued to be the ruling principle of his life. In childhood he was very delicate, and was brought up in the most retired manner. He showed no interest in the boisterous sports of youth, and even shunned the society of his fellows. He remained in this dull, dreamy condition until his ninth year, when a dangerous illness shook his faculties from their slumber, and called forth the energies of a genius of uncommon power and originality. His elementary education was now prosecuted with great success; and he displayed an extraordinary fondness for history and poetry. The Traditionary Tale (*Märchen*), which he afterwards continued to admire, had at this early stage a peculiar charm for him; and one of his earliest literary endeavours was a composition of this sort, written for the amusement of his brothers and sisters. After a few months at a gymnasium, he repaired to Jena in 1790, where he prosecuted his studies for three years. He then removed with his brother Erasmus to the university of Leipsic, and after spending a season there, went to Wittenberg to complete his education. It seems to have been Jena, however, which exerted the most marked influence over his development. Here he first met Friedrich Schlegel, and it was here he first listened to the lofty eloquence of Fichte. The *Wissenschaftslehre*, or Doctrine of Science, of that distinguished thinker, was studied by Novalis with singular avidity. The charm of its refined idealism attracted the sympathies of an intellect of surprising subtilty; the stern grandeur of its morality called forth the enthusiasm of the youthful romanticist; and the burning eloquence and calm dignity of the teacher carried conviction to the heart of the student. The philosophy of Fichte formed accordingly the groundwork of all the subsequent speculations of Novalis. The Kantian distinction, and even occasional antagonism, of the Understanding and the Reason, is carried by him into all departments of mental development—into poetry, virtue, and religion. He learned to despise with the transcendentalists the dull, blind, pedestrianism of the Understanding, and sought to gain the citadel of truth by following the clear, steady light of the higher Reason. The whole of his writings have a constant reference to this specula-

Novalis.

Novalis.

tive theory, and can only be studied in the light of it. After displaying a strong predilection for a military life, his friends succeeded in prevailing on him to follow his father's occupation; and he accordingly removed to Arnstadt in Thuringia in 1794, to train himself for business. Having remained a year there, he was appointed auditor of the department of which his father was director, and took up his residence at Weissenfels. In the year 1797 events occurred which, according to his biographer Tieck, gave a shock to his whole nature, and imparted a gloomy complexion to his thoughts, from which he was not destined to recover. During his residence at Arnstadt he had become enamoured of a fair, delicate German girl, possessed of uncommon attractions, but with health exceedingly fragile. He had hardly known her a year when the chill spring winds came and withered the fair flower; and ere he had time to dry his tears, he had to follow the remains of his brother Erasmus to the grave. It was during this year that the greater number of those remarkable pieces of Novalis, called *Hymns to the Night*, were composed. Not a few of his *Fragments* also belong to the same period. In 1798 he removed to Freyberg to study mineralogy under the famous Werner. In the mathematical and physical sciences he took an eager interest; and if we may judge from the fragmentary papers which he has left, he seemed to have prosecuted the study on a great and original principle. He put together about this time his unfinished "physical romance" of *Lehrlinge zu Sais*, or the Pupils at Sais, so full of strange poetized philosophy and shadowy allegorical allusion. While here he formed another betrothment, destined like the first to be cut short by death. On his return to Jena he made the acquaintance of August Wilhelm Schlegel and Tieck, then engaged in the famous literary campaign in behalf of what is generally known as Romanticism. Tieck "re-awakened poetry in him," he says; and it was in conjunction with these men, whose cause he ardently espoused, that Novalis first presented his thoughts to the world. He contributed his *Blüthens- taub*, or Pollen of Flowers, together with numerous poetical pieces, to the *Musen-Almanach* of F. Schlegel; and composed about the same time his *Geistliche Lieder*, or Spiritual Songs, so remarkable for simple sublimity and still, devout pathos. In addition to his passionate love of nature, these were perhaps his highest poetic gifts. In the summer of 1800 we find him living at a solitary spot at the foot of the Kyffhäuser Mountain in Thuringia, busily engaged on his art romance of *Heinrich von Ofterdingen*, designed, as he said, to be an "apotheosis of Poetry." It was never completed, however, and was ere long published in its unfinished state. In his prose style he generally aims at simplicity and directness—qualities not always to be found in his poetry. Indeed, it may be questioned whether, with all the wealth of a truly regal genius, he was possessed of the highest faculties of the poet. If in the rich strength of his theosophic mysticism he resembles an oriental, the likeness is increased when we regard the soft passiveness of his mind and character. Carlyle, who calls him the "German Pascal," says, "The chief excellence we have remarked in Novalis is his, to us, truly wonderful subtlety of intellect; his power of intense abstraction, of pursuing the deepest and most evanescent ideas through their thousand complexities, as it were with lynx vision, and to the very limits of human thought." (*Miscellanies*, vol. ii., p. 95.) In August 1800, while Novalis was preparing for a journey to Freyberg to bring home his betrothed, he was seized with a spitting of blood, which ended in a rapid decline. Hope, gladness, and rich expanding activity had just begun to make life desirable to him, when death came with the spring of 1801, and ended his strange career, at the premature age of twenty-eight. A Life of Novalis, by his friend Tieck, will be found prefixed to

Novalis Schriften, herausgegeben von Ludwig Tieck und Friedrich Schlegel, 2 vols., Berlin, 1802, and since frequently republished. A new edition of his Works, with various additions previously unpublished, appeared at Berlin in 1846, under the care of Tieck and Bulow.

NOVARA, a town in the Kingdom of Sardinia, capital of a division and province of the same name, stands on a rising ground between the Agogna and the Terdoppio, 53 miles E.N.E. of Turin. It is well built, containing several good and well-paved streets; and was formerly surrounded by walls, but these have now nearly all disappeared. The cathedral is an ancient and handsome building, with a square tower surmounted by a cupola, and contains in the interior several fine paintings and sculptures. The church of St Gaudenzio is likewise a fine structure, and contains one of the best paintings of Gaudenzio Ferrari. Besides these and other churches, Novara contains public offices, a town-house, court-house, an episcopal palace and seminary, several upper schools, a theatre, hospital, barracks, and market-house. The manufactures of the place are not very extensive, and consist chiefly of leather, cotton cloth, candles, starch, pottery, and biscuits. The principal trade is in silk and rural produce, for the latter of which Novara is the chief emporium in Piedmont. Near the town a battle was fought in 1849, in which the Sardinians were totally defeated by the Austrians under Radetzky. The result of this engagement was the resignation of the crown of Sardinia by the king, Carlo Alberto, and the renunciation of the Sardinia claims on Lombardy. Pop. about 16,000.

The division of Novara is bounded on the N. by Switzerland and the Alps, E. by Lake Maggiore and the Ticino, S. by the Po, and W. by the divisions of Turin and Ivrea. Towards the N.W. it is occupied by the branches of the Alps; but the greater part consists of a fertile plain, watered by the Fosa, Sesia, Terdoppio, Agogna, Ticino, and other smaller streams. Corn, rice, hemp, pulse, &c., are grown here; and on the higher regions the vine is largely cultivated. The division of Novara is subdivided as follows:—

Provinces.	Area in sq. miles.	Pop. (1848).
Novara.....	533	178,069
Lomellina.....	480	139,649
Pallanza.....	312	64,030
Ossola.....	520	36,331
Valsesia.....	290	35,879
Total	2135	453,958

NOVA SCOTIA, a British province of North America, situated between N. Lat. 43. 25. and 46. 0., and W. Lon. 61. 0. and 66. 30., and connected with the S.E. part of the continent by an isthmus of only 8 miles in width. It is bounded on the N. by the Strait of Northumberland, which divides it from Prince Edward's Island; on the N.E. by the Gut of Canseau, which interposes between it and the island of Cape Breton; on the S. and S.E. by the Atlantic Ocean; on the W. by the Bay of Fundy; and on the N.W. by New Brunswick. Its extreme length, from Cape Canseau on the E. to Cape St Mary's on the W., is about 280 miles; but its breadth varies from 50 to about 100 miles; and it contains a superficies of 15,607 square miles. From this, however, about one-fifth may be deducted for lakes, arms of the sea, and rivers, leaving about 8,000,000 acres of land, the greater part of which is still uncleared, and covered with forests.

The most remarkable characteristic of this peninsula is Surface. the numerous indentations along the coasts. The shores are lined with rocks, and studded with thousands of small islands; and close to these, and in the harbours, almost without exception, there is a considerable depth of water. All along the S.E. shore there is a succession of noble harbours; and vessels sail amongst and within the myriads of islands which line the coast during the most blustering

Scotia.

Nova
Scotia.
Surface.

weather, thus enjoying comparatively smooth water, whilst the main ocean heaves in violent agitation. The principal inlets are Sheet Harbour, Halifax Harbour, Margaret's Bay, Mahon Bay, Shelburne Harbour, on the Atlantic; St Mary's Bay, 10 miles broad and 35 long; Annapolis Basin, 10 miles in length, and from 1 to 4 in breadth; Mines Basin, 50 miles long, and 16 broad at the widest part, on the Bay of Fundy, which is terminated by Chignecto Bay, between Nova Scotia and New Brunswick; Pictou Harbour, on Northumberland Strait; St George's Bay, on the Gulf of St Lawrence; and Chedabucto Bay, on the Gut of Canseau. Between Halifax and Cape Canseau there are said to be no less than twelve harbours capable of accommodating ships of the line, besides fourteen others accessible for merchantmen. The interior of the country is very agreeably diversified with hill and dale, river and lake, forest and grassy plain. The surface, although undulating, is not mountainous; the highest land, Ardoise Hill or Arthur's Seat, being only 810 feet above the level of the sea, nearly the same height as Arthur's Seat at Edinburgh. The high lands generally run parallel to the coasts, branching off in all directions, and in some instances terminating in bold cliffs on the coast, the most remarkable of which is Aspotagoen, between Mahon and Margaret's Bay, which is about 500 feet in height. A tract of rugged and hilly country stretches along the shore of the Atlantic, varying in breadth from 20 to 60 miles, and having an average height of about 500 feet. The North Mountains, which are washed by the Mines Basin, extend along the coast of the Bay of Fundy, and terminate in Cape Blomidon; and parallel to these run the South Mountains in the interior of the peninsula. The Cobequid Hills extend from the northern shores of Mines Basin towards Northumberland Strait, having a breadth of 10 miles, and a height of about 800 feet. There are several remarkable caverns and grottoes in Nova Scotia, one of which, at St Peter's Point, on the coast of the Bay of Fundy, displays in the interior a spacious hall, the roof of which is fretted with stalactites.

Rivers and
Lakes.

The interior of Nova Scotia is intersected and watered by numerous rivers, lakes, and streams, which beautify and enrich the country. The two largest rivers are the Annapolis and the Shubenacadie. The former takes its rise in King's County, and, running parallel with the Bay of Fundy, after a long and serpentine course, in which it receives the Moose and Bear Rivers, discharges itself into Annapolis Bay. It is navigable to a considerable extent, and its banks present a rich and pleasing landscape. The Shubenacadie, issuing from the Grand Lake in the county of Halifax, divides that county from Hants, and, after a rapid and circuitous course, the length of which has not yet been accurately ascertained, discharges itself into the Bay of Mines. It receives the waters of ten other rivers, is navigable for large vessels a long way into the interior, and contains on its banks inexhaustible quantities of gypsum and lime, together with extensive groves of fine timber. At Pictou, three rivers, navigable for large vessels, empty themselves into the harbour; the East, West, and Middle Rivers. Besides these, there are the Avon, navigable for a considerable distance; the La Have, which issues from a chain of inland lakes, and has a course of about 60 miles; the Mersey, which winds from Lake Rosignol through the Queen's county, and discharges itself into Liverpool Harbour; the Medway, the Shelburne, the Clyde, the Tusket, the St Mary, and others, all of which owe their origin to lakes in the interior. A canal, called the Shubenacadie Canal, together with a chain of lakes, forms a communication by water across the peninsula from Halifax Harbour to Cobequid Bay, at the head of the Mines Basin. The most extensive still sheet of water is the Rosignol, situated partly in each of the three counties of Queen, Shelburn, and Annapolis. It is said to be 30

miles in length, but is little known. Lake George is also of considerable size; and there are innumerable others which it is unnecessary to mention.

Nova
Scotia.

The climate of Nova Scotia was for many years after its discovery considered as an insuperable barrier to agricultural industry, and an idea long prevailed in England that it was peculiarly the region of snow and fog. The temperature is indeed colder in winter in this peninsula than it is in Great Britain; but when the weather is cold it is usually dry; and altogether the winter is milder, and the summer less intensely hot, than at Quebec. The summer heat is moderate and regular; the autumn is a delightful season; and there is seldom any severe winter weather until the end of December. Frost continues generally from Christmas to April, and the spring is of very short duration. The temperature varies during the year from 6° or 8° Fahr. below zero, to 80° above it, the average of the coldest month at Halifax being about 20°, and that of the hottest about 70°. Like other parts of North America, however, Nova Scotia is subject to sudden changes of temperature, sometimes as much as 50° in twenty-four hours. The mildness of the climate seems to be owing in some degree to the influence of the gulf-stream, which prevents the harbours on the Atlantic from being frozen up in winter like those on the northern coast.

There is a great variety of rocks in Nova Scotia, but granite, trap, and clay-slate predominate. The most abundant variety is the gray granite, which, together with gneiss and mica-slate, prevails along the shore, and is well adapted for mill-stones. Trap rocks, sometimes imbedded in clay-slate, protrude in various places in immense parallel ridges above the surface, and frequently in piles of loose masses heaped confusedly together, traversed frequently by veins of quartz. Clay-slate of a very fine quality, and used as a building stone, prevails in the eastern section of the colony; and graywacke and graywacke-slate extend along both shores of Chedabucto Bay, in which are found beds of limestone and numerous specimens of specular iron ore. In connection with carboniferous limestone are found, both in Cape Breton and Nova Scotia, those immense coal-fields which are supposed to rival in extent the mines of the mother country. The coal is of a bituminous character, and entirely different from that which is found in the United States, east of the Appalachian Mountains. It is of various kinds, some of which are well fitted for the use of the smith, others for that of steamboats, and others for gas-making. In the coal formations of this country there is also found an immense quantity of gypsum, which is largely exported to the United States. Varieties of copper, iron, and lead ores are also abundant; and different other minerals of less importance are found. Fine specimens of agates, amethysts, chalcedonies, jaspers, and other stones, are obtained in Nova Scotia. Salt springs, some of them strongly impregnated with saline matter, are met with near Pictou, at River Philip, and some other parts.

The wild animals are the moose, cariboo, bear, lynx, fox, marten, otter, mink, beaver, musk-rat, porcupine, racoon, weasel, squirrel, hare, and the like, all of which, excepting the two last, have rapidly decreased in number. Nearly all the birds common to North America frequent Nova Scotia; and there are but very few kinds of fish which are found in the American seas that do not frequent the shores of this colony in vast swarms. The lakes and rivers abound in trout and salmon.

The soil is of many different qualities, and various degrees of fertility. The alluvial or intervale lands, of which there are extensive tracts, are rich, and produce plentiful returns of wheat, barley, oats, Indian corn, potatoes, turnips, with all the vegetables and fruits common in England. Some of the uplands, lying between the hilly country and the rivers, are light and poor; whilst the high

Nova
Scotia.

lands are rich and very productive. The lands on the Atlantic coast are generally so rocky as to admit of cultivation only at much expense and labour; but after the stones are removed, the soil is by no means barren. The forests of Nova Scotia still constitute a prominent feature of the country. The trees are the same as those common to America, and the timber is generally large and lofty.

Agricul-
ture.

Agriculture is carried on to a considerable extent in Nova Scotia. The cultivated ground consists partly of the rich alluvial marshes on the shore of the Bay of Fundy, and partly of the uplands in the interior of the country. The former kind of ground, which has been recovered from the sea by means of dykes, was estimated in 1850 to amount to 40,012 acres; and the latter to 799,310 acres. The produce in 1852 was 297,157 bushels of wheat, 196,097 of barley, 61,438 of rye, 1,384,437 of oats, 170,301 of buckwheat, 37,475 of maize, 21,638 of pease and beans, 3686 of grass seeds, 1,986,789 of potatoes, 467,127 of turnips, 32,325 of other roots, 287,837 tons of hay, 3,613,890 lb. of butter, and 625,069 lb. of cheese. The amount of live stock in the same year was 28,789 horses, 156,857 neat cattle, 86,856 milch cows, 282,180 sheep, and 51,533 swine.

Sable
Island.

Sable Island, although distant about 85 miles from Nova Scotia, is considered as belonging to that province. It lies directly in the track of vessels bound to or from Europe, and has been the scene of numerous and melancholy shipwrecks. It is 25 miles in length, by about $1\frac{1}{2}$ in breadth, the eastern end being in Lat. 43. 59. N., and Long. 59. 45. W. It is a barren desert throughout, the soil consisting chiefly of sand, and the only vegetable productions being a coarse grass and some wild pease. A sum, which amounted in 1854 to L.1977, is annually devoted to keeping on the island a superintendent from Nova Scotia, with a party of men provided with provisions and other necessaries, for the purpose of affording assistance to any shipwrecked mariners, of whatsoever nation, who may be driven on its inhospitable shores. There is a small stock of cattle on the island, and a large number of wild horses, but the chief supplies of food are obtained from Nova Scotia.

Manufac-
tures and
commerce.

The manufactures are few in number, consisting principally of coarse cloth, flannel, carpets, hats, paper, tobacco, leather, spirits, and agricultural implements. The province contained in 1850, 1153 saw-mills, employing 1786 hands; 386 grist-mills, employing 437 hands; 10 steam-mills; 237 tanneries; 9 foundries; 81 carding and weaving establishments; 17 breweries and distilleries; and 131 other manufactories of various sorts. In the same year there were raised in Nova Scotia 114,992 chaldrons of coal; there were quarried 79,795 tons of gypsum, valued at L.10,498; 28,603 casks of lime, valued at L.4433, were burned; 2,845,400 bricks, valued at L.3211, were made; and 110,441 lb. of maple sugar were produced. In the same year the value of leather manufactured was L.52,625; of boots and shoes, L.73,654; of iron smelted, L.4635; of castings, L.3486; of soap, L.28,277; and of candles, L.21,210. Ship-building is also carried on in Nova Scotia. The number of vessels constructed in 1854 was 244, and their tonnage 52,814. Besides farming, the chief occupation of the inhabitants is fishing; and some combine both pursuits. There were in 1851 employed in the fisheries of Nova Scotia and Cape Breton 812 vessels, with a tonnage of 43,333, and manned by 3681 men; 5161 boats, with 6713 men; and the number of nets and seines was 30,154. The quantity of fish cured was 196,434 quintals; and there were also obtained 1669 barrels of salmon; 3536 of shad; 100,047 of mackerel; 53,200 of herring; 5343 of alewives; and 15,409 boxes of smoked herrings, valued at L.217,270; as well as 189,250 gallons of fish oil, valued at L.17,754. The total value of the fisheries is estimated to exceed

L.200,000. The exports of the province consist principally of fish, sugar, molasses, rum, cotton and woollen goods, timber, &c. The total value of the exports in 1854 was L.1,247,668. The principal articles imported are flour, sugar, tea, manufactured goods, &c.; the total value of the imports in 1854 was L.1,791,082. The number and tonnage of the vessels that entered and cleared in 1851 were as follows:—

Nova
Scotia.

Countries.	Entered.		Cleared.	
	Ships.	Tons.	Ships.	Tons.
United Kingdom	107	47,744	74	38,728

Total	3402	340,039	3247	338,038

The executive power in Nova Scotia is in the hands of a Govern-
ment. lieutenant-governor, and a council of six members. The legislature consists of a council of nineteen, appointed by the governor, subject to the approval of the crown; and a House of Assembly, of fifty-one members, elected by the people. The system of responsible government has been established in Nova Scotia since 1848. The lieutenant-governor has a salary of L.3000 a-year. The judicial establishment consists of a supreme court, composed of a chief-justice and four assistant judges; which sits at Halifax three times a-year, and makes two annual circuits of the province; a court of error, composed of the lieutenant-governor and executive council; a court of chancery; courts of general sessions of the peace; courts of vice-admiralty; a court of marriage and divorce; and courts of probate. The established religion is Episcopa-
Religion. lian: Nova Scotia was created a diocese in 1787, and has a bishop, an archdeacon, and fifty other clergymen; the two first being supported by an endowment from the home government, and the others by the Society for the Propagation of the Gospel. The amount of public expenditure for ecclesiastical purposes in 1854 was L.3687. There is a Synod of Nova Scotia in connection with the Established Church of Scotland, and various churches in connection with the Free Church of Scotland and the United Presbyterian Church. The Roman Catholic Church has two dioceses, Nova Scotia and Cape Breton, within the province. The whole number of churches in 1851 was 567; and the adherents of the various denomination, were as follows:—

Church of England.....	35,482	Baptists.....	42,243
Church of Scotland.....	18,967	Methodists.....	23,596
Free Church of Scotland.....	25,280	Congregationalists.....	2,639
United Presbyterians.....	28,767	Lutherans.....	4,087
Roman Catholics.....	69,631	Other sects.....	4,660

Nova Scotia contains several colleges, besides inferior
Education. educational establishments. King's College at Windsor resembles the English universities, and Dalhousie College at Halifax those of Scotland. There are also a Free Church college, a Baptist college, and a Roman Catholic college. None of the attempts which have been made to unite some of these colleges into a university has proved successful. Each of the counties in the province has a grammar school; and the total number of schools in Nova Scotia in 1851 was 1096, attended by 31,354 scholars. The amount of public money expended on education in 1854 was L.13,401.

The military forces of the province consist of twenty-six Army-
regiments of militia, 26,248 strong, but which might soon be raised to nearly double that number. Besides this, Nova Scotia is protected by two or three regiments of the line, which are always stationed in the garrison towns, and by the visits during the summer of the squadron of the Royal Navy. The principal fortifications in the province

Novatianus are at Halifax, at Windsor, at Annapolis, and at Cape Breton. The revenue is chiefly derived from a duty on imported goods, and amounted in 1854 to L.166,501, while the expenditure for the same year was L.169,159.

Inhabi-
tants.

The inhabitants of Nova Scotia consist of English, Scotch, Irish, Americans, Germans, Swiss, Acadian French, Indians, and freed Negroes. They mingle and live together in much harmony, and generally the social state of the province is rapidly improving. Its prosperity has greatly increased; and, instead of importing, it now exports provisions. Its fisheries, to which proper attention is at length paid, its rich and prolific soil, and its mines of coal and iron, are sources of wealth which were too long neglected by Great Britain.

The province is divided into eighteen counties, including Cape Breton, as follows:—

Counties.	Pop. (1851).	Capitals.
Halifax.....	39,112	Halifax.
Lunenburg.....	16,395	Lunenburg.
Queen's.....	7,256	Liverpool.
Shelburne.....	10,622	Shelburne.
Yarmouth.....	13,142	Yarmouth.
Digby.....	12,252	Digby.
Annapolis.....	14,286	Annapolis.
King's.....	14,138	Kentville.
Hants.....	14,330	Windsor.
Cumberland.....	14,339	Amherst.
Colchester.....	15,469	Truro.
Pictou.....	25,593	Pictou.

Cape Breton }	27,580	{ Sydney.
Victoria }		{ Bedeque.
Total.....	276,117	Halifax.

History.

Our limits will only admit of a brief abstract of the history of Nova Scotia. Ancient authorities state that it was discovered by the Cabots in 1497; but it was not until 1604 that the French attempted to form settlements. They were, however, expelled from it in 1614 by the English colonists of Virginia, who claimed the country in right of the discovery of Sebastian Cabot. In 1621 Sir William Alexander obtained a grant of the whole peninsula, and it was named in the patent Nova Scotia, instead of Acadia, as the country was called by the French. In the meantime the latter obtained a footing in it a second time; and it was not until 1654, when a strong force was despatched by Cromwell, that the French settlers were brought under subjection. In 1667 Nova Scotia was ceded to France by the treaty of Breda; but, after suffering during the war which broke out in 1701, as well as previously, it was finally ceded to England by treaty in the year 1711. From this period till 1749 it was neglected by Great Britain; but the designs of the French called the attention of government to the province. Encouragements were held out to settlers; Parliament gave a large grant; and about 4000 adventurers, with their families, embarked for the colony. Halifax was immediately founded; but the French settlers, under the name of neutrals, were still very numerous; and, with the aid of the Indians, they inflicted repeated injuries upon the British, until they were forcibly expelled by the latter. In 1758 a constitution was granted to Nova Scotia; and the capture of Louisburg, in the island of Cape Breton, during the same year, gave additional security to the colony, which now began to improve. By the treaty of Paris, 10th of February 1762, France resigned all further claims on any of her former possessions in North America, and nothing of any material importance has since occurred. New Brunswick and Cape Breton were separated from Nova Scotia, and formed into two distinct governments, in 1784, but the latter was re-annexed to Nova Scotia in 1819.

NOVATIANUS, the founder of the sect of the Novatians, was, according to Philostorgius, a native of Phrygia,

Nova
Zembla.

and was born about the beginning of the third century. The religious intolerance of his opponents has falsified his life, and has represented him as little else than a hypocritical time-server. But the account which is most consistent with the growth of his peculiar opinions is the following:—His conversion took place after an intense mental struggle, and he was baptized when he was lying on a sick-bed, in hourly expectation of death. On his recovery, his religious sentiments retained a tinge of that gloom under which they had sprung into life. Admitted into the priesthood, he devoted himself to the severe theological studies and the ascetic penances of the cloister. It is not surprising, then, that his spirit was shocked at the easy terms on which those who had relapsed into idolatry during the Decian persecutions were re-admitted into ecclesiastical communion. He began to maintain boldly that the church had no warrant from Scripture to pardon the sins of those who, after their baptism, had sacrificed to idols: that her sole duty in this case was to exhort them to repentance, and to commend them to the mercy of God. The learning, eloquence, and virtuous life of the new reformer soon drew a party around him. Among others, Novatus, a Carthaginian priest, joined the dissentients, and by his hot-headed zeal speedily hurried the controversy into an open schism. Advantage was taken of the martyrdom of Fabianus, Bishop of Rome, in 250, to disown the authority of Cornelius, the successor to the vacant see, and to set up Novatianus as his rival. The result was, that at a council convened at Rome in 251, the Novatians and their leader were excommunicated. Thus compelled to organize a new sect, the heresiarch set himself to develop his peculiar opinions. The following became the distinguishing tenets of his creed:—(1.) That not only sacrificing to idols, but all mortal sins, such as adultery and temporizing in any way with idolatry, ought to debar backsliders from re-admission into the church. (2.) That if this regulation were not maintained, the church would become defiled, and would no longer be (as it ought to be) a community of believers who had never fallen since their baptism into any other than venial offences. This testimony Novatianus is said to have sealed with his blood. After his death, his followers, in spite of much persecution, rapidly increased and spread themselves over Christendom. They continued to vindicate their right to be considered the true church, by calling themselves *καθαρὰι* (*Puritans*), and by re-baptizing all proselytes from other Christian sects. However, they did not maintain their existence as a separate sect for much longer than two centuries.

Of the several works in which Novatianus displayed his methodical reasoning, his pure and elegant diction, and his animated style, three authenticated writings alone remain. These are a letter written in the name of the Roman clergy to Cyprian in 250, and two treatises entitled respectively *De Trinitate*, and *De Cibis Judaicis*. They have been published collectively by Welchman, 8vo, Oxford, 1724, and by Jackson, 8vo, London, 1728. The two treatises are also generally found in the editions of Tertullian.

NOVA ZEMBLA, or NOVAIA ZEMLIA, a name which signifies in Russian "New Land," is applied to an island, or rather chain of islands, in the Arctic Ocean. It extends from N.N.E. to S.S.W., curving slightly towards the W., and lies between N. Lat. 70. 30. and 76. 30., E. Long. 51. 30. and 77. It is washed on the W. by the Spitzbergen Sea, and on the E. by the Kara Sea; which, along with Burrough's Strait, separates Nova Zembla from the continent and from the island of Vaigats. Its whole length is about 500 miles, with an average breadth of about 50. The most southerly island of the chain is separated from the rest by a strait called Matochkin Shar, or Matthew's Strait; and farther to the N. there is another strait called Cross Bay, which divides itself into several arms, and forms other small islands. The southern island alone is properly called

Novel
||
Novgorod.

Nova Zembla; the middle one, which is much smaller, is known by the name of Matthew's Land; while to the N. lie Lütke's Land and Barent's Land, believed to form one continuous island. The eastern shores of all the islands are low; but on the W. the land is mountainous, rising in general 2000 feet above the sea, and the highest summit, near Matthew's Strait, is 3475 feet in height. The formation of the mountain is for the most part black clay-slate; and in the southern islands grey limestone, like that of the northern part of the Ural chain. The climate of these islands is indicated by the following table:—

Place.	N. Lat.	E. Lon.	Mean Annual Temp.	Mean Summer Temp.	Mean Winter Temp.
South extremity.	70. 37.	57. 47.	14°-99	35°-59	3°-21
Matthew's Strait.	73. 0.	57. 20.	16-93	38-49	2-29
Cross Bay.....	74. 0.	58. 0.	20-74	36-60	9-78

The vegetation is very scanty, consisting only of mosses and lichens; in many parts the ground is quite barren; and notwithstanding the long continuance of the sun above the horizon, the soil is never thawed more than a foot or two deep. Animal life is as scarce here as vegetation. Nova Zembla is often visited by fishermen from Archangel in pursuit of the walrus. It was visited at an early period by the Russians, but was first brought into notice by Steven Burrough, who made a voyage thither in 1556. The west and part of the east coast were visited in 1596 by the Dutch navigator Barents; and several Russian expeditions have been sent out from Russia within the present century to explore the islands.

NOVEL. See ROMANCE, part ii.

NOVELDA, a town of Spain, province of Alicante, and 15 miles W. of the town of that name. The streets are pretty regular, and the houses, which are mostly of stone, are generally well built. Some trade in fruit and agricultural produce is carried on; and after agriculture, distilleries and oil-mills principally afford employment to the population, which amounts to about 9000.

NOVELLARA, a town of Northern Italy, duchy of Modena, and 16 miles N.W. of the town of that name. It is the capital of a principality annexed to Modena in 1737; and carries on some silk and leather manufactures. Pop. 4100.

NOVEMBER, the eleventh month of our modern year, was the ninth in the old Roman calendar. On this account the name *November* or *Novembris* (from *novem*, nine) was assigned to it in the Alban calendar. It consisted originally of thirty days, but Julius Cæsar added one to it. Augustus, however, again reduced it to its original number, which it has ever since retained. (See CALENDAR.)

NOVGOROD, or NOVOGOROD, a government of Russia, lying between N. Lat. 57. 18. and 61. 8., E. Long. 30. 10. and 39. 40.; and bounded on the N. by Olonetz, E. by Vologda and Yaroslavl, S. by Tver, and S.W., W., and N.W. by Pskov and St Petersburg; area, 46,833 square miles. The country is diversified with hills, valleys, plains, marshes, rivers, and lakes; the northern part is in general low and flat; but in the south the Valdai hills stretch for about 100 miles from S.W. to N.E., though these do not exceed 300 feet in height. The principal rivers are the Msta, which enters the government from Tver, flows north-west, and falls into Lake Ilmen; the Lovat, Pola, and Schelen, which fall into the same lake; the Volchov, which flows from that lake into the Ladoga Canal; the Schekona and Vologda, tributaries of the Volga; and the Sias and Buscha, which fall into Lake Ladoga. There are altogether in the government forty-two rivers, and fifty-five small, besides three large lakes. Of these last, the most extensive is the Bielo Osero, or White Lake, in the north-east, which is 26 miles in length, about as much in breadth, and 432 square miles in extent. Lake

Ilmen, near the western extremity, has a length of 26 miles, a breadth of 16, and an area of 846 square miles; and Lake Vosche has a length of 14 miles, and an area of 177 square miles. There is a canal, 5 miles in length, connecting the rivers Msta and Volchov, by which navigation is carried on without passing through Lake Ilmen, as that extensive sheet of water is liable to dangerous storms. The soil in the southern parts is good and productive; but in the north it is very swampy, consisting for the most part of peat bogs. The climate is cold, and the winter long, lasting from November to May; while in the northern parts the cold is extreme, and the winter about a month longer than in the south. A large part of the land is covered with dense forests of pine, fir, birch, alder, elm, and other trees, which supply abundance of timber for export, and give shelter to great numbers of deer, elks, bears, wolves, lynxes, and other wild animals. The people are chiefly engaged in agriculture; and the principal crops are rye, barley, oats, buckwheat, potatoes, pease, flax, and hemp. Although there is much fine pasture ground, the inclemency and length of the winters prevent the rearing of more cattle than is necessary for farming; horses, oxen, and sheep of the common Russian breeds, and a few goats and pigs, are kept. Next to agriculture, fishing is the most general occupation of the people; it is carried on with great success on the lakes and rivers. Coal, iron, freestone, slate, lime, marl, &c., are among the mineral produce of Novgorod; and there are also good salt springs. The manufactures are not very extensive; and consist of coarse linen, soap, candles, potash, &c. Distilling, iron-smelting, and bell-making are also carried on. The exports of the province consist entirely of home produce, especially corn, hemp, flax, iron, timber, salt, hides, and furs. The principal place of trade is Novgorod, the capital. The government is divided into ten circles. Pop. (1846) 907,900.

NOVGOROD, the capital of the above government, stands on the Volchov, where it issues from Lake Ilmen, 120 miles S.S.E. of St Petersburg. It is one of the most ancient towns in Russia, having been founded in the fifth century of the Christian area by the Slavonians, who had long previously invaded Europe, and followed a wandering mode of life. Their government was at first democratic, but dissensions having broken out and greatly weakened their power, Ruric was invited in the ninth century to assume the government, and he established at Novgorod the original foundation of the Russian monarchy, the seat of which was soon afterwards removed to Kiev. Novgorod afterwards acquired many privileges from the Russian archdukes; and in the twelfth century became an independent republic under a hereditary magistrate of limited power. In the thirteenth century a factory of the Hanseatic League was established here; and for a long time Novgorod was the most important commercial city in the north-east of Europe. Its fairs were resorted to by the Hanse merchants, and by people from all the neighbouring countries; and in the fifteenth century it is said, though not probably with truth, to have contained 400,000 inhabitants. Indeed, so great was its power and prosperity at this time as to give rise to the saying, "*Quis contra Deum et magnam Novgorodiam.*" But this did not last long; for in 1477 its independence was completely destroyed by Ivan Vassilievich I.; and in 1570 Ivan IV. took occasion, from a treasonable correspondence of some of the citizens with Poland, to massacre more than 25,000 of the inhabitants. The trade of the place was still considerable, until the foundation of St Petersburg, which monopolized the Baltic trade, and completely destroyed the importance of Novgorod. It now presents most unmistakeable marks of fallen greatness in its ruinous buildings, dilapidated walls, and grass-grown streets. The Kremlin, or fortress, stands on the north side of the river, and is connected by a fine stone

Novgorod-
Sieversk
||
Nowan-
uggur.

bridge with the commercial town and *Sophiskaia* on the other side. There are numerous churches, the principal of which is the cathedral in the Kremlin; three monasteries, a bazaar, a palace, a poor-house, and an orphan school. Sail-cloth, leather, soap, and candles are manufactured. Pop. 16,781.

NOVGOROD-SIEVERSK, a town of Russia, capital of a district in the government of Tschernigov, stands on the right bank of the Desna, 109 miles E.N.E. of Tschernigov. It is surrounded by walls, and has a castle, but neither is in a good state of repair. An active trade in corn, hemp, and lime is carried on; and several large fairs are held annually. Pop. (1849) 10,544.

NOVI, a town of Northern Italy, capital of a cognominal province in the division of Genoa, is situated in the plain of Marengo, at the foot of the Apennines, 25 miles N.N.W. of Genoa. It is surrounded by an old dilapidated wall; and of its old castle few remains now exist. The streets are irregular and narrow; but in the centre of the town is a handsome square adorned with a beautiful marble fountain. The principal public building is an ancient church, a fine old edifice with two towers; and some of the old houses are noted for their picturesque appearance. It is the seat of civil and commercial tribunals; and has a college, two monasteries, a theatre, and foundling hospital. Novi has an active trade; and carries on various manufactures, the chief of which is silk, for which it is one of the most celebrated places in Italy. In the neighbourhood a severe action took place in 1799 between the French and Austro-Russians, in which the former were defeated. Pop. 10,500. The province has an area of 288 square miles, and contained, in 1848, 65,013 inhabitants.

NOVI-BAZAR, a town of European Turkey, capital of a cognominal sanjak in the government of Bosnia, is situated on the Rashka, 180 miles S.E. of Bosna-Serai. It is a place of some trade; and has several warm baths. Pop. about 8000.

NOVICE, a person not yet skilled or experienced in an art or profession. In the ancient Roman militia, *novicii* or *novitii* were the young raw soldiers, distinguished by this appellation from the veterans. In the ancient orders of knighthood there were novices or clerks in arms, who went through a kind of apprenticeship ere they were admitted knights. Novice is more particularly used in monasteries for a religious person in his or her noviciate or year of probation, and who has not taken the vows. In nunneries the novices wear a white veil, the rest a black one. The custom of giving novices the religious dress was not known before the twelfth century. The Council of Trent fixed the age of profession at sixteen years.

NOVO-REDONDO, a seaport-town and fort of S.W. Africa, belonging to the Portuguese. The town occupies the summit of a rock at the mouth of the River Redondo, and is inhabited almost solely by free Negroes.

NOVO-TSCHERKASK, a town of European Russia, capital of the country of the Don Cossacks, on the River Don, about 40 miles from its mouth. It was founded in 1806 in consequence of the unhealthiness of old Tscherkask, the then capital. It is the seat of the government offices; and is well laid out with broad and regular streets, the houses being generally of one storey. It has a cathedral and numerous other churches, a college, and several schools, and a large hospital. Pop. (1850) 17,875.

NOWAGURH, a raj of India, subject to the political agent for the S.W. frontier. Its centre is in Lat. 20. 20. N., Long. 82. 25. E.; and it has an area of 1512 square miles. Pop. estimated at 68,000. The country is said to be among the worst governed of those within the circle to which it belongs.

NOWANUGGUR, a town of India, peninsula of Katwyar, province of Guzerat, 310 miles N.W. of Bombay.

It stands on a creek indenting the S. shore of the Gulf of Cutch; and carries on a great trade, being the principal place of the district of Hallar, which is estimated to contain a population of 207,680. The town itself is nearly 4 miles in circuit, and is celebrated for its manufactures of fine cloth, as well as for the dyes given to that article. Copper ore has been discovered in a range of hills in the vicinity.

NOX, one of the most ancient deities among the heathens, and the personification of Night. She was daughter of Chaos, and from her union with her brother Erebus, she gave birth to the Day and the Light. She was also the mother of the Parcae, Hesperides, Dreams; of Discord, Death, Momus, Fraud, &c. Nox is called by some of the poets the mother of all things, of gods as well as of men; and Homer makes her the subduer of gods and men, Zeus himself being awed by her. (*Il.* xiv.) She was worshipped with great solemnity by the ancients, and had a famous statue, executed by Rhæcus, in the temple of Diana at Ephesus. It was usual to offer her a black sheep, as she was the mother of the Furies; and a cock was also presented to her, as that bird proclaims the approach of day during the darkness of the night. She is represented as mounted on a chariot, and covered with a veil bespangled with stars. The constellations generally went before her as her constant messengers. Sometimes she is seen holding under her arms two children, one of which is black, representing Death, and the other white, representing Sleep. Some of the poets have described her as a woman veiled in mourning, crowned with poppies, and on a chariot drawn by owls and bats. (See Hesiod, *Theog.*; Euripides, *Orestes* and *Ion*; also Pausanias.)

NOY, Sir WILLIAM, an attorney-general, whose conduct was one of the great causes of the civil war in England, was born in 1577. During the former part of his career his sentiments were patriotic, and he was distinguished in Parliament as one of the most formidable opponents of the despotism of Charles I. No sooner, however, had he been appointed attorney-general in 1631, than he was suddenly transformed into one of the most pliant tools of the king. The legal knowledge and ingenuity of the political apostate began to be employed in extorting from the constitution certain precedents which might countenance the tyranny of his royal master. He consummated his treachery to his country by devising the project of levying ship-money. But before he had seen the disasters which that act of his contributed to bring upon the land, he died, in 1634. Among his valuable legal works are, *A Treatise of the Principal Grounds and Maxims of the Laws of England*, of which the seventh edition was published in 12mo, 1806; and *The Compleat Lawyer*, of which the latest edition was published in 8vo, 1674.

NOYON (anciently *Noviomagus*), a town of France, department of Oise, on the Vorse, a tributary of the Oise, 42 miles E.N.E. of Beauvais. The town is ancient, but well built; and is surrounded with numerous gardens. It was formed into a bishopric in 531; and its cathedral is a fine Romanesque edifice of the twelfth and thirteenth centuries. Charlemagne resided here; and Hugh Capet was here elected king of France in 987. Noyon is, however, chiefly remarkable as the birth-place of the Reformer John Calvin. Manufactures of linens, hosiery, leather, &c., are carried on, and a brisk general trade. Pop. 6322.

NUBIA, a large country of Africa, lying between Egypt on the N. and Abyssinia on the S., the Red Sea on the E. and the Great Desert on the W.; and extending from N. Lat. 11. to 24., E. Long. 25. to 36. The name, however, is not always applied to the whole of this region, but is restricted by some geographers to the country east of the Nile, while the natives themselves apply the terms *Nooba*, or *Wady-el-Nooba*, to a comparatively small por-

Nox
||
Nubia.

Nubia.

Character
of the
country.

tion between Derr and Dongola. It is about 850 miles in length, and upwards of 600 in breadth; while its area is estimated at 360,000 square miles.

The aspect of the country in Lower Nubia is very different from that of Egypt, though both alike form part of the valley of the Nile. The mountains, which consist chiefly of sandstone and granite, approach much nearer to the river, leaving only a narrow strip of arable land along the water's edge; and the rocks in some places extend into the bed of the river, forming rapids, the lowest of which, called the First Cataract, occurs at the confines of Egypt and Nubia. Beyond the hills which line the river on either side stretches the desert of Nubia, extending on the one side to the Red Sea, and on the other being separated from the Sahara only by inconsiderable hills and table-lands. In some places the desert comes quite close to the Nile, forming sandy banks to the river, and in other places the banks are covered only with a thin strip of vegetation. Upper Nubia occupies the lowest of the three table-lands which are supposed to constitute this part of the African continent. The elevation increases towards the southern border of Nubia, which has a height of 4000 feet above the sea. This district is also occupied by several mountain chains, which do not for the most part, as in Egypt, extend parallel to the river, but from west to east, forming numerous valleys in the same direction. Of these chains the most important are the Gebel Snigrè, Gebel Safieha, and Orbay Langay; the last of which stretches from Faka on the Albara to Suakim on the Red Sea, and has numerous offshoots in the eastern Nubian desert. A range of mountains stretches along the coast of the Red Sea, but these are not very high, nor in any way remarkable. Coarse grey granite, quartz, and mica-slate are the chief geological formations of Upper Nubia. Gold and silver mines are said to exist near the shores of the Red Sea; but all the attempts made by the Pasha of Egypt to work them have proved fruitless. In Upper Nubia the Nile is not so closely shut in by mountains as in the lower region; and this country is also watered by other rivers, which discharge their waters into it. At the Second Cataract immense plains stretch out from either margin of the stream, exhibiting, it is said, even in their present neglected condition, unequivocal indications of fertility; and as there seems to be little doubt that in former ages the annual inundation extended considerably beyond the limits of modern cultivation, so it may reasonably be presumed that anciently the country was much more productive and populous than in modern times, when the decrease of the inundation, and the continual encroachment of the moving sands of the desert on either side, have combined to produce the desolation which now prevails. At present the Nile seldom or never overflows its banks in this part of Nubia; and the portion of the soil cultivated is irrigated by means of *sakheas*, or Persian wheels constructed for raising the water of the river to the level of the adjacent ground. The eastern bank of the Nile is much better adapted for cultivation than the western, being more easily irrigated by artificial means. But it is not a little remarkable, that all the splendid ruins for which this region is distinguished, and which exhibit so great labour, ingenuity, and skill, are found upon the opposite bank; a circumstance which seems to strengthen the presumption that Nubia was formerly much more fertile and populous than in the present day.

Divisions
of Nubia.

The country on the banks of the Nile is composed of two parts,—Wady Kenoos and Wady Nooba, so called from the tribes who inhabit them, and who differ from each other in language. The former extends from the confines of Egypt on the south to Wady Sebooa; and the latter, from which the general name of the country appears to have been derived, stretches as far as the frontier of Dongola. The chief distinction between these two parts consists in

the circumstance, that the languages spoken in each are entirely different.

Nubia.

The grain which forms the principal object of Nubian cultivation is *dhourra*, the *Andropogon sorghum* of botanists. It is raised upon the patches of soil irrigated by means of the *sakheas* or Persian wheels, of which there are from 600 to 700 between the First and Second Cataracts; and, when ground, it is formed into a cake somewhat resembling the Abyssinian *teff*. After the *dhourra*, the Nubians raise a crop of barley, French beans, lentils, and sometimes also of water-melons. Sometimes a third crop is raised in the year, and this in these cases generally consists of *dhourra* again. Tobacco is everywhere cultivated, and constitutes the principal luxury of all classes, being either smoked or sucked in a peculiar manner between the gums and the lip. Animal food is scarce, and seldom eaten, even by the chiefs or sheiks. The liquors used are palm-wine, a spirit distilled from dates, and a sort of beer called *boozza*, which is made from *dhourra*. Excessive indulgence in these liquors is general throughout the whole country. The only fruit trees cultivated in Nubia are palms, but the soil is adapted for several others. Great sameness prevails in the vegetation of the desert, the trees being mostly acacias, tamarisks, date and doum palms.

The climate of Nubia, though intensely hot in summer, is nevertheless remarkably healthy. This is no doubt a consequence of the extreme dryness of the atmosphere, occasioned by the absence of rain and the absorbent qualities of the soil. The upper regions of Nubia, however, are by no means destitute of rain, but are exposed from March to May to those showers which cause the overflowing of the Nile. They do not extend N. of 17. 30. N. Lat. The plague has seldom or never reached Wady Halfa, and beyond the Second Cataract it is entirely unknown. The small-pox, however, is a fearful scourge, and, owing to the ignorance and filthiness of the people, occasionally commits dreadful ravages.

Climate.

The people are now generally known by the name of Nubians, and are called by the Arabs *Barabra*. They consist of the Kenoos and Nooba tribes, and differ considerably in appearance at different places, those to the south being much darker than the inhabitants of the country bordering on Egypt. They are generally well made, strong, and muscular, and have tolerably good features. The women are not handsome, but perfectly well formed, and in general remarkable for agreeable countenances and pleasing manners. Great numbers of the Nubians repair to Cairo, where they usually act as porters, and are esteemed for their honesty; but they always return to their native villages with the little property which they have saved in plying their humble vocation. They excel the Egyptians in honesty and veracity, though they are inferior in acuteness. They are likewise distinguished for their brave, independent, and patriotic spirit. The inhabitants of Derr-el-Mahas and the more southerly districts differ considerably from the other Nubian tribes. They are of Arab descent, and speak the language and follow the wandering life of that people.

Popula-
tion.

Previously to 1821 the Nubians were independent, being ruled by chiefs of their own; but in that year they were brought under the power of the Egyptian pashas; and the government of Nubia is now, like that of Egypt, a military despotism. Some trade is carried on in Nubia, Sennaar and Shendy being the principal marts for the commerce of eastern Africa. The principal articles of export to Egypt are dates, which are obtained here of an excellent quality; gold, ivory, ebony, and slaves are imported into Nubia from the interior of Africa, and thence sent to Egypt, Arabia, or the East; and the principal imports through Egypt are soap, sugar, beads, coral, paper, and hardware.

Govern-
ment and
commerce.

One of the most remarkable features of this region consists in the magnificent monumental remains with which it

Nubia.
Monu-
mental re-
mains of
Nubia.

is covered along the line of the stream, and which continue to perpetuate the genius and power of the ancient population of the country situated on the Upper Nile. The principal remains in Nubia, beginning with the lowest down on the river and proceeding upwards, are the following:—At Dabod on the W. bank, 15 miles above the First Cataract, are the remains of a temple, dedicated, according to a Greek inscription over the entrance, by Ptolemy Philometer and his queen Cleopatra, to Isis and other deities. The temple of Kalabshee, whose ruins stand on the same side of the Nile, about 29 miles above Dabod, is the largest in Nubia. It does not seem to be earlier than the time of Augustus, though the materials have apparently been taken from an older building. The body of the temple consists of three parts, and has twelve columns in front. It stands in the middle of an inclosure, which is entered by a portico with two pyramidal towers. At the same place is an ancient temple of the age of the Pharaohs, cut out of the rock, and adorned with elegant sculptures. The temple of Dendoor, which stands just within the tropic, is believed to have been founded by Augustus in honour of Osiris, Isis, and Horus. At Dakkeh, further up than Dendoor, are the remains of a temple founded by Ergamun, an Ethiopian king of the age of Ptolemy Philadelphus. On the opposite side there are extensive brick ruins, bearing the names of Remeses VII. and VIII., who lived in the twelfth century B.C. The ruined structure at Sabooa has before it a propylon, with two pyramidal towers. The pronaos on each of its longest sides has five columns without capitals, and in front of each is a colossal figure, 16 feet in height, with the arms crossed on the breast, and the usual emblems in the hands. In front of the propylon are two statues, 10 feet in height, with their faces towards the river, and attached by the backs to stone pillars of equal elevation: and an avenue of sixteen sphinxes leads from the bank of the Nile to the temple. The whole fabric appears to be of the remotest antiquity, and is ascribed to the age of Remeses the Great (1355–1289 B.C.) Of the same era is the temple of Derr, which, has some bold though defaced sculptures.

But of all the temples of Nubia, that of Abou-Simbel Ebsamboul or Ipsamboul, about 40 miles below the Second Cataract, is incomparably the most remarkable. It has the finest colossal figures of any in Egypt, which, notwithstanding their great size, have countenances of considerable beauty, when seen from a proper distance. The great hall contains eight pillars with colossal figures attached to them, and there are many other apartments opening into it. Both the pillars and the walls are covered with representations of battles, storming of castles, triumphs, and sacrifices, in a style, if not superior to, at least bolder than, that of almost any in Egypt, both in regard to the design and the workmanship. The second hall, which is of less dimensions, contains four pillars about 4 feet square, and the walls are covered with hieroglyphics in tolerable preservation. Beyond this there is a chamber of the same width, but shorter, in which is the entrance to the sanctuary; and at each end is a door leading into smaller apartments in the same direction with the adytum. The sanctuary itself is 23 feet in length by 12 in breadth, and contains a pedestal in the centre, with four colossal figures in a sitting posture at the end, all in good order and uninjured. The outside or external front of this temple is truly magnificent, being 117 feet in width, and 86 feet in height, whilst the space from the top of the cornice to that of the door is 66½ feet, and the height of the door itself 20 feet. There are four enormous sitting figures, the largest in Nubia, or even in Egypt, excepting only the great sphinx at the Pyramids, to which they approach in the proportion of nearly two-thirds. On the top of the door is a statue of Osiris, 20 feet in height, with a colossal figure on each side looking towards it. The cornice of the temple is adorned with hieroglyphics, and

Nuddea.

under it are a torus and frieze, the one 6 and the other 4 feet in breadth. Above the cornice is a row of squatted monkeys, twenty in number, and each 8½ feet across the shoulders. This temple was nearly two-thirds buried in the sand till the year 1817, when the sand was cleared away, and an entrance obtained by Belzoni, Irby, Mangles, and Beechey. In several places of the square border which encircles the front of the temple, and also on the buttresses between the colossal figures, are a number of ovals or rings, containing the name and prænomén of Remeses the Great, the same Pharaoh whom the Greeks indicate by the name of Sesostris or Sethosis.

The temples at Samneh, situated on the western bank of the river, between the twenty-first and twenty-second degree of north latitude, afford specimens of a more perfect class of structures; intermediate, it would seem, between such excavations as that of Ebsamboul and the magnificent edifices of Karnak and Luxor. That on the eastern bank has a portico and a hall running parallel to it, behind which are three small and one larger chamber; and that on the other side is more elegant, consisting of one chamber surrounded by a corridor of pillars.

The first architectural attempt in Nubia probably was the improvement of some hole or cave in the rock; or even if the country possessed no natural caves for imitation by a people possessing the troglodyte habits natural to the inhabitants of a burning climate, the mountains themselves would afford facilities for constructing durable habitations. After having got possession of a hole or cave, the next step of these primitive architects would probably be to extend the excavation, to form several chambers separated by the native rock, and when a compartment of larger dimensions was designed, to have square pillars for the support of the roof. In the course of time the outer front, with the inner walls and pillars, would receive decorations derived from imitations of the natural forms of the country, and subjects connected with the historical remembrances or religious creed of the nation. We see abundant evidence in the rock-temples of Nubia to convince us that the order of progression and improvement here indicated was that actually followed in their gradual enlargement and decoration; yet a prodigious period must have elapsed between the rudest excavation in the rock, such as Derr appears to have been in its primitive state, and the highly-finished sculptures of the great temple of Ebsamboul. In fact, “antiquity appears to have begun” long after these primeval architects had commenced their troglodyte labours. But, in surveying the wonders which crowd the banks of the Nile from Meroë to Memphis, our minds become insensibly impressed with the reflection, that the wealth, power, and genius which produced them have entirely passed away; that, if new worlds have risen, and new races been discovered, “we have lost old nations;” and that, in the lapse of ages, empires themselves vanish, like the baseless fabric of a vision, leaving scarcely a wreck or trace behind them. The contrast between what now is and what once must have been in Ethiopia and in Egypt, is indeed most striking; nor is it easy to pass, even in thought, through the various scenes of conquest and desolation which must have conspired to produce the effects we contemplate. History sheds no light on events and characters which the lapse of 3000 years has covered with impenetrable obscurity; and whilst groping our way amidst temples dedicated to gods, and structures raised in honour of heroes, whose very names sound like voices from the dead, we content ourselves with the conclusion, which all the monuments impress on us, that long before the dawn of history there had existed in that singular region a great people, whose architectural monuments have outlasted their learning, their philosophy, and almost even their very name.

NUDDEA, a district of British India, under the lieu-

Nuddea
||

erianus.

tenant-governor of Bengal, comprised within the delta of the Ganges, and lying between Lat. 22. 49. and 24. 10. N., and Long. 88. 9. and 89. 11. E. It is about 90 miles in length from N. to S., by 45 in breadth, and has an area of 2942 square miles. The soil is well watered and highly fertile, producing in abundance rice, millet, maize, pulse, oil-seeds, sugar-cane, indigo, tobacco, and hemp. Pop. 298,736.

NUDDEA, a town of British India, in the district of Burdwan, at the commencement of the Hooghly River, 80 miles N. of Calcutta, Lat. 23. 25. N., Long. 88. 22. E. It was the capital of a Hindu principality anterior to the Mogul conquest of Hindustan, and was taken and entirely destroyed in 1204. In modern times it has been the seat of a Brahmin seminary of learning; anterior, however, to that of Benares.

NUGEENAH, a town of British India, division of Rohilcund, North-West Provinces, in Lat. 29. 27. N., Long. 78. 30. E. It is noted for its manufactures of fire-arms; and contains about 14,000 inhabitants.

NUISANCE, or NUSANCE, in law, a thing done to the annoyance of another. Nuisances are either public or private. A public or common nuisance is an offence against the public in general, either by doing what tends to the annoyance of all the king's subjects, or by neglecting to do what the common good requires; in which case, all annoyances and injuries to streets, highways, bridges, and large rivers, as also disorderly ale-houses, gaming-houses, and the like, are held to be common nuisances. A private nuisance is, when only one person or family is annoyed by the doing of anything; as when a person stops up the light of another's house, or builds in such a manner that the rain falls from his house upon his neighbour's. In Scotch law, there is no recognised distinction between public and private nuisances.

NUMA POMPILIUS, the successor of Romulus on the throne of Rome, was the son of an illustrious Sabine, and was raised to the imperial dignity by the unanimous voice of the Roman senate and people. After a remarkably popular reign of 42 years, during which he endeared himself both to his own people and to the surrounding nations by his great abilities and singular humanity, Numa died in the year of Rome 82. (See ROMAN HISTORY.)

NUMANTIA, a very noble city, the ornament of the Hither Spain, and celebrated for the long war of 20 years which it maintained against the Romans. The inhabitants obtained some advantage over the Roman forces, till Scipio Africanus was empowered to finish the war, and to effect the destruction of Numantia. The town occupied an eminence of great steepness, and was approachable only on one side. Scipio began the siege with an army of 60,000 men, and was bravely opposed by the besieged, who were no more than 4000 men able to bear arms. They held out against the enemy with the most indomitable courage while their provisions lasted; but being reduced to desperation, they set fire to their houses, and destroyed themselves, so that not even one remained to adorn the triumph of the conqueror. It was taken by the Romans 134 B.C., and the conqueror obtained the surname of *Numanticus*. It is conjectured that the modern Puente de Garay, near Soria, marks the site nearly of this once famous city. Fragments of antiquity are occasionally dug up there. (Accounts of this memorable siege are to be found in Appian, *B. Hisp.* 48, &c.; Eutropius, iv.; Cicero, *De Off.*; Strabo, iii.; also in the *Compendio Historiæ*, b. iii., of Pedro Tutor y Melo, Soria, 1690.)

NUMERALS. See ARITHMETIC.

NUMERIANUS, MARCUS AURELIUS, a Roman emperor, succeeded to the purple conjointly with his elder

brother Carinus, on the death of his father Carus, A.D. 284, and was murdered in the same year, after a reign of eight months. (See ROMAN HISTORY.)

NUMIDIA, an ancient country of Africa, which owed its name to the circumstance that its early inhabitants were pastoral tribes (*Numádes*). These tribes, differing both in descent and character, extended their wanderings from the Nile along the coast as far west as the Fortunate Islands. The limits of the country were therefore for a long time very ill-defined. It was not until the time of the Punic wars that the title of Numidians came to be definitely restricted to the Massæyli and the Massyli, who dwelt between the River Mulucha (*Malouia*) on the W., and the Carthaginian territory on the E., and were divided from each other by the River Ampsaga (*Wad-el-Kebir*). These two tribes were then athletic and warlike savages, living on the sides of the mountains in little huts called *magalia*, and scouring the plains on horseback without saddle or bridle. From that period, however, the character of the people, and the condition of the country, began to be changed by foreign interference and the events of war. During the struggle between Hannibal and the Romans, Syphax, the prince of the Massæyli, espoused the cause of the former, and Masinissa, the prince of the Massyli, espoused the cause of the latter. Syphax was defeated, along with his great ally, in the battle of Zama, B.C. 202; his territories were incorporated with those of the Massyli; all the Carthaginian district, with the exception of a portion around the capital city, was added; and Masinissa received possession of the whole, with the title of King of Numidia. It then became the aim of that able prince to civilize his people by the introduction of arts and agriculture. After his death in 148 B.C., the same line of policy was followed, with even more success, by his son and successor Micipsa. But the commotions that broke out in the ensuing reign marred the prosperity which a long peace had been fostering. Jugurtha, the nephew, and Adherbal and Hiempsal, the sons of Micipsa, were left joint-heirs to the throne. The first of these princes was unscrupulous and ambitious, and did not rest until he had defeated and murdered his cousins, and had seized the sceptre of the entire kingdom. This involved the Numidians in a contest with the Romans. After all the wiles of intrigue and the stratagems of war had proved unsuccessful, the usurper was captured and put to death in 106 B.C., and the crown was bestowed upon Hiempsal II. But the disasters of Numidia were not yet ended. Juba I., the son and successor of the last-mentioned prince, espoused the cause of Pompey during the Roman civil war. The final defeat of his party at the battle of Thapsus, in 46 B.C., left him exposed to the vengeance of Cæsar. The desperate state of his affairs drove him to commit suicide; and his kingdom, reduced into the form of a Roman province, was placed under the governorship of Sallust the historian. Soon after this period Numidia began to enter upon a long period of prosperity. The "jus coloniæ" was conferred upon its capital, Cirta (*Constantina*), and upon its other chief towns—Rusicade, Hippo-Regius (*Bona*), Sicca (*Keff*), Lambæsa, and Theveste. Commerce was diffused by means of the Roman roads; peace was preserved by means of the Roman soldiers; and the wild Numidian horsemen were thus transformed in course of time into a community of industrious peasants. The gospel found an easy entrance, and prospered so rapidly, that the country is said to have contained in the fifth century no fewer than 123 episcopal sees. It was not until the invasion of the Saracens, in the seventh century, that the prosperity of Numidia, simultaneously with its Christianity, received a fatal blow. (See ALGERS. For further information regarding Numidian history, see also MASINISSA, MICIPSA, JUGURTHA, and JUBA I.)

NUMISMATICS.

INTRODUCTION.

Introduction. THE science of Numismatics treats of coins and medals.¹ It acquaints us with the metals used in their composition, their various inscriptions and devices, their mechanical execution and artistic merit. It tells us of the different denominations of coins, with their relation to one another, and the laws by which they were regulated.

Definition. The earliest known coins were issued by the Greeks, most probably in the eighth century before the Christian era.² By the fourth century the whole civilized world used money, each state generally having its proper coinage. This has continued to be the case to the present time; so that now there are few nations without a metal currency of their own, and of these but a small proportion are wholly unacquainted with the use of coins. The number of varieties of coins and medals of which specimens are preserved in collections may be estimated at not less than 200,000;³ and future discoveries will probably greatly raise this sum. A series of monuments of such length and completeness affords, as might be expected, very important illustration to history and to kindred branches of knowledge. This is, indeed, the real value of Numismatics; and the student will do well to keep it constantly before him, for thus he will be saved from the narrow view of a mere collector, by which many have been led in a false direction, and so discredit has been brought upon the science.

Coins and medals. Coins, although they confirm history, rarely correct it, and never very greatly. The earliest belong to a time and to nations as to which we are not otherwise wholly ignorant, and they do not afford us that precise information that would fill in any important details of the meagre sketch of contemporary history. We gain from them scarcely any direct historical information, except that certain cities or princes issued money. When, in later times, the devices and inscriptions of the coins give more detailed information, history is far fuller and clearer, so that the numismatic evidence is rarely more than corroborative. There are, indeed, some remarkable exceptions to this rule, as in the case of the Bactrian coins, which have supplied the outlines of a portion of history which was otherwise almost wholly lost. The value of the corroborative evidence afforded by coins must not, however, be overlooked. It chiefly relates to chronology, although it also adds to our knowledge of the pedigrees of royal houses. But perhaps the most interesting manner in which coins and medals illustrate history is in their bearing contemporary, or nearly contemporary, portraits of the most famous kings and captains, from the time of the first successors of Alexander the Great to the present age: whereas pictures do not afford portraits in any number before the latter part of the middle ages; and works of sculpture, although occupying, in this respect, the same place as coins in the last-mentioned period and under the Roman empire, are neither so numerous nor so authentic. There is no more delightful companion in historical reading than a cabinet of coins and medals. When we know the features of Alexander and Mithradates, of Julius Cæsar and Augustus, of the Antonines and Severus, we can far more readily take ourselves back to the times in which they lived, and feel a real interest in their stories. Our belief in the truth of history is confirmed by the qualities we can perceive in their portraits. The strength and energy of Alexander, the brilliant genius of Mithradates, the philosophic calmness of Antoninus, the obstinate ferocity of Nero, and the brutality of Caracalla, are as plain on the coins as in the pages of history. The numismatic portraits of the time following the founding of Constantinople have less individuality; but after the revival of art they recover that quality, and maintain it to our own day, although executed in very different styles from those of antiquity. From this last class we can form a series of portraits more complete and not less interesting than that of the ancient period.

Introduction. While coins and medals thus illustrate the events of history, they have an equally direct bearing on the belief of the nations by which they were issued; and in this reference lies no small part of their value in connection with history. The mythology of the Greeks not having been fixed in sacred writings, nor regulated by a dominant priesthood, but having grown out of the different beliefs of various tribes and isolated settlements, and having been allowed to form itself comparatively without check, can scarcely be learned from ancient books. Their writers give us but a partial or special view of it, while even modern authors, in their attempts to systematize, have often but increased confusion. The Greek coins, whether of kings or cities, until the death of Alexander, bear sacred subjects only. Afterwards, on the regal coins, the king's head usually occupies the obverse, and a sacred subject is placed on the reverse. About this period the local myths begin to lose their special character, through the destruction of the small independent states, and the centralized system of the great empire and the kingdoms which sprang from it. The earlier coins afford us invaluable evidence for the reconstruction of Greek mythology. We have nowhere else so complete a series of the different types under which the divinities were represented. There are in modern galleries very few statues of Greek divinities, including such as were intended for architectural decoration, which are in good style, fairly preserved, and untouched by modern restorers. If we add to these, bas-reliefs of the same class, and the best Græco-Roman copies, we can scarcely form a complete series of the various representations of these divinities. We cannot take ruder or baser works, since we should be led into error by them. The coins, however, supply us with the series we desire, and we may select types which are not merely of good work, but of the finest. The mythology of ancient Italy, as distinct from that of the Greek colonies, is not so fully illustrated by the coins of the country, because these are for the most part of Greek design. There are, however, some remarkable exceptions, especially in the money of the Roman commonwealth, the greater number of the types of which are of a local character, including many that refer to the myths and traditions of the earliest days of the city. The coins of the empire are especially important, as bearing representations of those personifications of an allegorical character to which the influence of philosophy gave great prominence in Roman mythology.

Coins are scarcely less valuable in relation to geography than to history. The position of towns on the sea, or on rivers, the race of their inhabitants, and many similar particulars, are positively fixed on numismatic evidence. The information that coins convey as to the details of the history of towns and countries has a necessary connection with geography, as has also their illustration of local forms of worship. The representations of natural productions on ancient money are of special importance, and afford assistance to the lexicographer. This is particularly the case with the Greek coins, on which these objects are frequently portrayed with great fidelity. We must recollect, however, that the nomenclature of the ancients was vague, and frequently comprised very different objects under one appellation, and that therefore we may find very different representations corresponding to the same name.

The art of sculpture, of which coin-engraving is the off-spring, receives the greatest illustration from Numismatics. Not alone is the memory of lost statues preserved to us in the designs of ancient coins, but those of Greece afford admirable examples of that skill by which her sculptors attained their great renown. The excellence of the designs of very many Greek coins struck during the period of the best art is indeed so great, that, were it not for their smallness, they would form the finest series of art-studies in the world. The Roman coins, though at no time to be compared

¹ This science cannot be considered to be a branch of Archæology, since it treats not only of ancient and mediæval coins, but of modern ones also.

² The Chinese place the commencement of their coinage at a very remote date, but this statement is unsupported by satisfactory evidence. All authentic specimens appear to be several hundred years later than the oldest Greek money. (See sect. vi., below.)

³ The collection of the British Museum now comprises upwards of 120,000 specimens; and during late years from 2000 to 5000 pieces have been annually added.

Introduction.

to the purest Greek, yet represent worthily the Græco-Roman art of the empire. From the accession of Augustus to the death of Commodus they are often fully equal to the best Græco-Roman statues. This may be said, for instance, of the dupondii struck in honour of Livia by Tiberius, and by the younger Drusus; of the sestertii of Agrippina; and of the gold coins of Antoninus Pius and the two Faustinas, which present portraits of remarkable beauty and excellence. The mediæval Italian medals are scarcely less useful as records of the progress and characteristics of art, and, placed by the side of the Greek and Roman coins, complete the most remarkable comparative series of monuments illustrating the history of the great schools of art that can be brought together. Ancient coins throw as great light upon the architecture as upon the sculpture of the nations by which they were struck. Under the empire, the Roman coins issued at the city very frequently bear representations of important edifices. The Greek-imperial coins, struck in the provinces, present similar types representing the most famous temples and other structures of their cities, of the form of some of which we should otherwise have been wholly ignorant. The little-known art of painting among the ancients does not receive any great illustration from the coins. The best Greek pieces are of too severe a style to admit of an approach to pictorial treatment, although we perceive such a tendency in the works of important schools, and during the period of decline. The Roman coins sometimes present groups which have a very pictorial character, traceable to the tendency of the sculpture of the period: this is principally about the time of the Antonines. They are never, however, so pictorial in treatment as the mediæval Italian medals. The art of gem-engraving among the ancients is perhaps most nearly connected with their coinage. The subjects of coins and gems are so similar and so similarly treated, that the authenticity of gems, that most difficult of archæological questions, receives the greatest aid from the study of coins. No one whose eye is acquainted with the treatment of figures by Greek and Roman medallists could suppose for a moment such works as those of the Poniatowski collection to be productions of ancient artists. It is probable, also, that coins not unfrequently supplied subjects to the old gem-engravers.

Literature. After what has been said, it is not necessary to do more than mention how greatly the study of coins tends to illustrate the contemporary literature of the nations which issued them. Not alone the historians, but the philosophers, and the poets are constantly illustrated by the money of their times. This was perceived at the revival of letters; and during the last two centuries coins were very frequently engraved in the larger editions of the classics. A want of technical numismatic knowledge in the editors, and the carelessness of the artists, combined to deprive these illustrations of much of their value. Probably in part on this account, but chiefly in consequence of the change from historical to textual criticism, ancient coins have been little used in this manner by the new school. This neglect is beginning to be remedied, although the full value of coins and medals in illustration of the literature of modern as well as ancient times is not as yet sufficiently perceived.

Origin of this science.

The science of Numismatics is of a comparatively recent origin. The ancients do not seem to have formed collections, although they appear to have occasionally preserved individual specimens for their beauty. Petrarch has the credit of having been the first collector; but it is probable that in his time ancient coins were already attracting considerable notice. The importance of the study of all coins has since been by degrees more and more recognised; so that at the present time no branch of the pursuit is left wholly unexplored. It cannot,

however, be said that the actual condition of the science justifies great expectations. We shall best perceive this if we inquire what objects it has to fulfil.

Besides its bearing upon the history, the religion, the manners, and the arts of the nations which have used money, the science of Numismatics has, from its relation to art, a special modern use, at which we have already hinted. Not alone do coins display the various styles of art prevalent at different ages, but in doing so they supply us with abundant means for promoting the advancement of art among ourselves. If the study of many schools be at all times of advantage, it is especially so when there is little originality in the world. Coins and medals have therefore two main uses, the one relating to the illustration of history, and the other to the promotion of art. It is not for these purposes that collections are usually formed. It is in vain to point to the high prices now paid for rare coins, if that rarity be not always accompanied by some marked historical or artistic importance. Very few among the collectors think of any thing beyond the rarity or the beauty of a coin, and of the latter they frequently judge by a vicious standard. So little have the coins themselves been thoroughly studied even by professed numismatists, that few of them have formed an opinion as to the different denominations to which many of the most common specimens correspond. The study of ancient coins, and that of ancient systems of coinage, have been more and more separated. There is also much reason to complain of the comparative neglect of various branches of Numismatics. Until equal attention be paid to all, the condition of the science cannot be called sound. Why, for instance, while the Roman money is eagerly collected and studied, is the Byzantine series, its proper continuation, and one of the most important portions of the mediæval class, generally treated with contemptuous neglect? Numismatics, thus superficially and partially pursued, demands the least labour and affords no result of importance, except the negative one of bringing into disrepute one of the most valuable aids to historical inquiry.

SECT. I.—DEFINITIONS.

The following are the most necessary numismatic definitions:—

1. A *coin* is a piece of metal of a fixed weight, stamped by authority of government, and employed as a circulating medium.¹
2. A *medal* is a piece struck to commemorate some event or person, and having no place in the currency. Medals are frequently comprised with coins in descriptions that apply to both equally: thus, in the subsequent definitions, by the term coins, coins and medals must generally be understood.
3. The coinage of a country is usually divided into the classes of gold, silver, and copper, for which the abbreviations *A*, *Al*, and *Æ*, are employed in catalogues. In each class are comprised not only the coins of the metal from which it takes its name, with no more than a necessary or inseparable proportion of alloy, but coins of other metallic substances, usually base, and always compound, which were generally struck in the place of the purer pieces. The principal metallic substances thus used were electrum for gold, billon for silver, brass for copper, and potin for silver and copper.
4. *Electrum* (ἤλεκτρον, ἤλεκτρος), a compound metallic substance, consisting of gold with a considerable alloy of silver. Pliny makes the proportion to have been four parts of gold to one of silver.² The material of early coins of Asia Minor struck in the cities of the western coast is the ancient electrum. It appears here to have first consisted of three parts of gold to one of silver; but afterwards the proportion of silver was increased, though perhaps not everywhere. Gold largely alloyed with silver, not struck by the ancient Greeks

¹ This definition excludes, on the one hand, paper currencies and their equivalents among barbarous nations, such as cowries, because they are neither of metal nor of fixed weight, although either stamped or sanctioned by authority, and, on the other hand, modes of keeping metal in weight, like the so-called Celtic "ring-money," as not stamped, although perhaps sanctioned by authority. The latter has attracted so much attention, that it must not be passed by without some further notice. There seems to be no reasonable doubt that the Celtic gold rings all weigh multiples of the same unit, but very seldom multiples of one another. From their form, it is probable that most of them were used as ornaments, and as such they would probably have been generally made to weigh an exact weight without fractions, on the same principle that the ancients frequently avoided fractions of their measures in architecture. They belong to a time anterior to the introduction of money among the Celts, or before its general use, and one, therefore, at which precious metal must have been weighed when employed in barter. Hence an additional reason, and probably the main one, why their weight is always some multiple of the same unit. In a primitive state of society in the present day, a woman often wears her dowry in coins as ornaments; and thus these Celtic rings may have been both ornaments and substitutes for money.

² *Hist. Nat.* xxxiii. 23; comp. xxxvii. 11. Pliny distinguishes two kinds of "electrum," amber, and this metallic substance. In Greek poetry the name seems to apply to both, but it is generally difficult to decide which is meant in any particular case. Sophocles, however, where he mentions τὸν χρὸς Σάφειον ἤλεκτρον, . . . καὶ τὸν Ἰνδικὸν Χρυσόν (*Ant.* 1087-1089), can scarcely be doubted to refer to the metallic electrum.

Definitions, or their neighbours, should be termed *pale gold*, as in the case of some of the late Byzantine coins.

5. *Billon*, a term applied to the base metal of some Roman coins, and also to that of some mediæval and modern coins. It is silver with a great proportion of alloy. When the base silver coins are replaced by copper washed with silver, the term *billon* becomes inappropriate.

6. *Brass*, a compound metallic substance employed for coins. It may be used as an equivalent to the *orichalcum* of the Romans, a fine kind of brass, of which the *sestertii* and *dupondii* were struck, but it is commonly applied indiscriminately to the whole of their copper currency.

7. *Potin*, a term applied to the base metal of which some ancient coins are composed. It is softer than *billon*.

8. Various other metallic substances have been used in coinage. The so-called "glass money" of the Arabs has not been proved to have borne any value, and if it had, it would be excluded with paper money and the like from the class of coins.

9. The forms of coins have greatly varied in different countries and at different periods. The usual form in both ancient and modern times has been circular, and generally of no great thickness.

10. Coins are usually measured by *Mionnet's scale*, from which the greatest dimension is taken, or when they are square, the greatest dimension in two directions. This is, however, a very unsatisfactory scale, as its divisions are of an arbitrary character, and the instruments for applying it are such as make exactness scarcely possible. A kind of gauge, graduated to inches and decimal parts of an inch, would be far more satisfactory.

11. The weight of a coin is of great importance, both in determining its genuineness and in distinguishing its identity. To ascertain exact weight to the tenth of a grain is therefore very necessary, and this can only be done by the careful use of excellent scales.

12. The specific gravity of a coin furnishes a ready means of determining the metal predominating in its composition.

13. Whatever representations or characters are borne by a coin constitute its *type*. The subject of each side is also called a type, and when there is not only a device but an inscription, the latter may be excluded from the term. This last is the general use. No distinct rule has been laid down as to what makes a difference of type, but it may be considered to be an essential difference, however slight.

14. A difference too small to constitute a new type makes a *variety*.

15. A coin is a *duplicate* of another when it agrees with it in all particulars but those of exact size and weight. Strictly speaking, ancient coins are rarely, if ever, duplicates, except when struck from the same die.

16. Of the two sides of a coin, that is called the *obverse* which bears the more important device or inscription. In early Greek coins, it is the convex side; in Greek and Roman imperial, it is the side bearing the head; in mediæval and modern, that bearing the royal effigy, or the king's name, or the name of the city; and in oriental, that on which the inscription commences. The other side is called the *reverse*.

17. The *field* of a coin is the space unoccupied by the principal devices or inscriptions. Any detached independent device or character is said to be in the field, except when it occupies the exergue.

18. The *exergue* is that part of the reverse of a coin which is below the main device, and distinctly separated from it: it often bears a secondary inscription. Thus, the well-known inscription CONOB occupies the exergue of the late Roman and early Byzantine gold coins.

19. The *edge* of a coin is the surface of its thickness.

20. By the *inscription* or *inscriptions* of a coin, all the letters it bears are intended: an inscription is either principal or secondary.

21. In describing coins, the terms *right* and *left* mean the right and left of the spectator, not the heraldic and military right and left, or those of the coin.

22. A *bust* is the representation of the head and neck: it is commonly used of such as show at least the collar-bone, other busts being called heads.

23. A *head* properly means the representation of a head alone, without any part of the neck, but it is also commonly used when any part of the neck above the collar-bone is shown. In the present article we have followed custom in the use of the terms *bust* and *head*.

24. A bust or head is either facing or in profile, in which latter case it is described as to *right* or to *left*. Two busts may be placed in various relative positions which cannot be described in English without circumlocution.

25. A bust wearing a laurel-wreath is said to be *laureate*.

26. A bust bound with a fillet is described as *with a fillet*. The term *diademed* is scarcely permissible.

27. A bust of which the neck is clothed is said to be *draped*.

VOL. XVI

28. An object in the field of a coin which is neither a letter nor a monogram is usually called a *symbol*. This term is, however, only applicable when such an object is evidently the badge of a town or individual. The term *adjunct*, which is sometimes employed instead of symbol, is manifestly incorrect.

29. A *mint-mark* is a difference placed by the authorities of the mint upon all money struck by them, or upon each new die or separate issue. This term is properly used only with reference to some mediæval and modern coins, since the mint-marks of ancient and oriental coins cannot be discriminated with any certainty.

30. A coin is said to be a *surfrappe* when it has been struck on an older coin, of which the types are not altogether obliterated.

31. A *double-struck* coin is one in which the die or dies have shifted so as to cause a double impression.

32. A coin which presents two obverse types, or two reverse types, or of which the types of the obverse and reverse do not correspond, is called a *mule*: it is the result of either a mistake or a caprice.

SECT. II.—ARRANGEMENT OF COINS.

No uniform system has as yet been applied to the arrangement of all coins. It is usual to separate them into the three great classes of ancient coins, comprising Greek and Roman; of mediæval and modern coins; and of oriental coins. The details of these classes have been differently treated, both generally and specially. The arrangement of the Greek series has been first geographical, under countries and towns, and then chronological, for a further division; that of the Roman series, chronological, without reference to geography; that of the mediæval and modern, the same as the Greek; and that of the oriental, like the Roman,—a treatment inadmissible except in the case of a single empire. Then, again, some numismatists have separated each denomination or each metal, or have separated the denominations of one metal and not of another. There has been no general and comprehensive system, constructed upon reasonable principles, and applicable to every branch of this complicated science. Without laying down a system of rules, or criticising former modes of arrangement, we offer the following as a classification which is uniform without being servile:—

1. *Greek Coins*.—All coins of Greeks, or barbarians who adopted their money, struck before the Roman rule, or under it, but without imperial effigies. The countries and their provinces are placed in a geographical order, from west to east, according to the system of Eckhel, with the cities in alphabetical order under the provinces, and the kings in chronological order. The civic coins usually precede the regal, as more important. The coins are further arranged chronologically, the civic commencing with the oldest, and ending with those bearing the effigies of Roman emperors. The gold coins of each period take precedence of the silver, and the silver of the copper. The larger denominations in each metal are placed before the smaller. Coins of the same denomination and period are arranged in the alphabetical order of the magistrates' names, or letters, &c., that they bear.

2. *Roman Coins*.—All coins issued by the Roman commonwealth and empire, whether struck at Rome or in the provinces, provided in the latter case that they are absolutely of the same character as the coinage of the city. The oldest proper Roman money is placed first, chronologically arranged; then that of the commonwealth, bearing the names of those who had the privilege of striking it, coins of all metals and denominations being placed under each family, and the families being put in alphabetical order; and, lastly, the coinage of each emperor, disposed either chronologically or geographically, according to the indications it offers, and without separation of denominations. An alphabetical arrangement of inscriptions must be resorted to in the family series and the imperial, when no other method can be followed, and in the smallest subdivisions, such as the coinage of one denomination issued in a particular year or by a particular mint.

3. *Mediæval and Modern Coins of Europe*.—All coins issued by European states, their branches and colonies, from the fall of the Empire of the West to the present day. This class is arranged in a geographical and chronological order, as similar as possible to that of the Greek class, with the important exception of the Byzantine coins and the coins following Byzantine systems, which occupy the first place. The reason for this deviation is, that the Byzantine money may be regarded not alone as the principal source of mediæval

Arrangement of Coins.

Greek
Coins.

coinage, but as the most complete and important mediæval series, extending as it does without a break throughout the middle ages. The regal coins usually precede the civic ones, as more important; and the medals of each sovereign or city follow the coins. The money of the Turkish empire is included in the oriental class.

4. *Oriental Coins.*—All coins bearing inscriptions in eastern languages, excepting those of the Jews, Phœnicians, and Carthaginians, which are classed with the Greek coins, from their close connection with them. These coins should be arranged under two great divisions, Pagan and Mohammadan,—the one nearly corresponding to the Greek and Roman class, the other to the mediæval and modern; for although the former includes modern coins, they are essentially similar to those of the ancient period. The first division is arranged for the most part according to the same general principles as the Greek series, the kingdoms being disposed geographically, and their sovereigns in a chronological order. It commences with the coinage of the Persian empire, and ends with that of China. The second division follows in general the same method of arrangement, with one important deviation, that the coins of the Umawee and Abbâsee Khaleefehs occupy the first place.

This method of arrangement will be found to be as uniform as it can be made, without being absolutely mechanical and servile. It differs in some important particulars from most or all of those which have previously obtained; but these very differences are the result of the consideration of a complete collection, and have therefore an inductive origin. A general uniformity is no slight gain, and may well reconcile us to some partial defects. These defects may be remedied in large collections by the use of "cross-references" from one cabinet to another, and by the formation of independent series to illustrate the general one. The latter suggestion is one that is well worthy careful consideration. A series illustrative of Greek art, and another of Roman art, might be formed. A series of portraits, and another of groups, would be equally valuable. Others might be made to show the changes of the coinage in relation to the condition of a state, with careful indications of the weight and composition of the examples, and to illustrate the history of a particular country or city. Thus, the Byzantine copper coinage exhibits the success or disaster of the imperial arms, and the financial state of the empire, in its fluctuations; while nothing can be more interesting than to see at one view the numismatic history of a great city. We have coins of Rome under the commonwealth and the empire, under the Ostrogoths, the Byzantines, the senate, and the popes. The series of London would be not the least curious. It would begin with the Roman coins issued by the mint of Londinium at the time of Diocletian and his colleagues, comprising those of the usurpers Carausius and Allectus; then, having ceased not long after for a time, it would recommence with the Saxon pennies, including a specimen of those of King Alfred, which have for their reverse type the monogram of the city's name; and, continuing through the mediæval period, it would conclude with modern tokens and medals, among the latter of which might be placed a copy of that famous one of the first Napoleon, with the inscription "Frappée à Londres," which was intended to commemorate the success of the Boulogne expedition.

SECT. III.—GREEK COINS.

There are some matters relating to Greek coins in general which may be properly considered before they are described in geographical order. These are their general character, their devices and inscriptions, the art of such as are not barbarous, the mode of striking, and the chief denominations, with the different talents of which they were the divisions.

The period during which Greek coins were issued was probably not less than a thousand years in length, commencing about the middle of the eighth century B.C.,¹ and generally ending at the death of Gallienus, A.D. 268. If classed with reference only to their form, fabric, and general appearance, they are of three principal types,—the archaic Greek, the ordinary Greek, and

the Græco-Roman. The coins of the first class are of silver, of electrum, and sometimes of gold. They are thick lumps of an irregular round form, bearing on the obverse a device, with, in some cases, an accompanying inscription; and on the reverse a square or oblong incuse stamp (*quadratum incusum*), usually divided in a rude manner. The coins of the second class are of gold, electrum, silver, and copper. They are much thinner than those of the preceding class, and usually have a convex obverse, and slightly concave or flat reverse. The obverse ordinarily bears a head in bold relief. The coins of the third class are, with very few exceptions, of copper. They are flat and broad, but thin, and generally have on the obverse the portrait of a Roman emperor. It may be observed that the common division of Greek coins is into autonomous and imperial, the former comprising all except those of the Roman period which have the effigies of emperors.

In choosing the types of Greek coins (using the term in its Devices, restricted sense), the first intention was, that they should indicate the city or state by which the money was issued. The necessity for distinctive devices was most strongly felt in the earlier days of the art, when the obverse of a coin alone bore a design, and, if any inscription, but the first letter, or the first few letters, of the name of the people by which it was issued. The motive which dictated the kind of type to be selected was undoubtedly a religious one. This position has been established in a conclusive manner by Mr Burgon in his *Inquiry into the Motive which influenced the Ancients in their Choice of the Various Representations which we find stamped on their Money*.² There are some isolated instances in which the religious character of a type is doubtful; but these, if proved, would be only exceptions to a general rule. The piety of that age adopted religious devices, and for a long time it was held to be impious to substitute any other representations for them. To the same cause may, perhaps, be partly ascribed the preference on the most ancient coins for devices of a symbolical character to actual representations of divinities; although the difficulty of portraying the human form in the infancy of art must have had considerable influence in this direction.

Greek coins, if arranged according to their types, fall into Classification, three classes,—1. Civic coins and regal, without portraits of sovereigns; 2. Regal coins bearing portraits; and, 3. Græco-Roman coins, whether with imperial heads or not. The coins of the first class have either a device on the obverse, and the *quadratum incusum* on the reverse, or two devices; and these last are again either independent of each other, though connected by being both local, or—and this is more common—that on the reverse is a kind of complement of that on the obverse. It will be best first to describe the character of the principal kinds of types of the first class, and then to notice their relation. It must be noted that a head or bust is usually an obverse type, and a figure or group a reverse one; and that, when there is a head on both obverse and reverse, that on the former is usually larger than the other, and represents the personage locally considered to be the more important of the two. We must constantly bear in mind that these types are local and religious, if we would understand their meaning. An observation of Mr Burgon, in the essay to which reference has just been made, puts this in a very clear light. "I do not believe," he says, "that the types of coins are, on any occasion, original compositions, but always copied (from the earliest to the lowest times) from some sacred public monument. Thus, when we find what is called a Boeotian buckler on coins, we are not to look upon the representation as a Boeotian buckler, but as the buckler of some Boeotian hero well known to the ancient inhabitants of that country, and accounted to be sacred by them. In like manner, when we find Minerva represented on coins, we are not to understand the type as a Minerva, but the Minerva of that place; and, in some cases which might be brought forward, the individual statues which are represented on coins, or ancient copies, will be found to exist. The only example of originality of composition apparent on coins is where types have been doubled or halved, to express similar modifications of value."³

Greek
Coins.General
character.

¹ It is extremely difficult to fix the age of the earliest coins known to us; but on the whole it seems most reasonable to assume for them the approximative date we have given. They may be somewhat older, but it is scarcely possible that they can be much later.

² *Numismatic Journal*, vol. i., p. 97, et seqq.

³ *Id.*, note 70, pp. 115, 116. The doubling of a type is also indicative of two sovereigns reigning together, or of a king and his queen, examples of both of which cases occur on the Ptolemaic coins.

Greek
Coins.

In the following list we have classified the types of Greek coins of cities, and of kings, not having regal portraits, in a systematic order, without referring to their relative antiquity:—

Coins with-
out regal
portraits.

1. Head or figure of a divinity worshipped at the town, or by the people, which issued the coin,—as the head of Pallas on coins of Athens, and the figure of Hercules on coins of Boeotian Thebes. Groups are very rare until the period of Græco-Roman coinage.

2. Sacred natural or artificial objects.

a. Animal sacred to a divinity of the place,—as the owl (Athens), and the tortoise (Ægina).

b. Sacred tree or plant,—as the silphium (Cyrene), and the olive-branch (Athens).

c. Arms or implements of divinities,—as the arms of Hercules (Erythræ), the tongs of Vulcan (Æsernia).

It is difficult to connect many objects comprised in this class with local divinities. The reason of this appears to be, that the Hellenes, wherever they colonized, and nowhere more than in Greece, found an earlier system of low Nature-worship, and endeavoured to incorporate it into their own more intellectual mythology, sometimes with but partial success.

3. Head or figure of a local genius.

a. River-god,—as the Gelas (Gela).¹

b. Nymph of a lake,—as Camarina (Camarina).

c. Nymph of a fountain,—as Arethusa (Syracuse).

4. Head or figure of a fabulous personage, or half-human monster,—as Medusa (Neapolis Macedonia), the Minotaur (Cnossus).

5. Fabulous animal,—as Pegasus (Corinth), a gryphon (Panticapæum), the Chimæra (Sicyon).

6. Head or figure of a hero or founder,—as Ulysses (Ithaca); the Lesser Ajax (Locri Opuntii); Taras, founder of Tarentum (Tarentum).

7. Objects connected with heroes.

Animal connected with local hero,—as Calydonian boar or its jaw-bone (Ætolians). Arms of heroes also occur as types, but their attribution to particular personages is difficult or impossible.

8. Celebrated real or traditional sacred localities,—as a mountain or hillock (Apollonia Illyrici), the Labyrinth (Cnossus).

9. Representations connected with the public religious festivals and contests,—as a chariot victorious at the Olympic games (Syracuse).

The relation of the types of the obverse and reverse of a coin is a matter requiring careful consideration, since they frequently illustrate one another. As we have before observed, this relation is either that of two independent objects, which are connected only by their reference to the same place, or the one is a kind of complement of the other. Among coins illustrating the former class we may instance the beautiful silver didrachms of Camarina, having on the obverse the head of the river-god Hipparis, and on the reverse the nymph of the lake carried over its waters by a swan; and those of Sicyon, having on the obverse the Chimæra, and on the reverse a dove. The latter class is capable of being separated into several divisions. When the head of a divinity occurs on the obverse of a coin, the reverse is occupied by an object or objects sacred to that divinity. Thus the common Athenian tetradrachms have on the one side the head of Pallas, and on the other an owl and an olive-branch; the tetradrachms of the Chalcidians in Macedonia have the head of Apollo and the lyre; and the copper coins of Erythræ have the head of Hercules and his weapons. The same is the case with subjects relating to the heroes: thus there are drachms of the Ætolians which have on the obverse the head of Atalanta, and on the reverse the Calydonian boar, or its jaw-bone and the spear-head with which it was killed. In the same manner the coins of Cnossus with the Minotaur on

the obverse, have on the reverse a plan of the Labyrinth. Besides the two principal devices, there are often others of less importance, which, although always sacred, and sometimes symbols of local divinities, are generally indicative of the position of the towns, or have some reference to the families of the magistrates who used them as badges. Thus, for example, besides such representations as the olive-branch, sacred to Pallas, on the Athenian tetradrachms, as a kind of second device dolphins are frequently seen on coins of maritime places; and almost every series exhibits many symbols which can only be the badges of the magistrates with whose names they occur. Regal coins of this class are usually of a local character, owing to the small extent of most of the kingdoms, which were rather the territories of a city than considerable states at the period when they were issued.

The second great class—that of coins of kings bearing portraits—is necessarily separate from the first. Religious feeling affords the clue to the long exclusion of regal portraits. It was not the result of that native horror of despotic power which made the early Greek kings or tyrants, from necessity or through policy, ape the character of citizens; but it was owing to a yet stronger feeling—the belief that it would be profane for a mortal to take a place always assigned hitherto to the immortals. Were there any doubt, it would be removed by the character of the earliest Greek regal portrait, that of Alexander, which occurs on coins of Lysimachus. This is not the representation of a living personage, but of one who was not alone dead, but had received a kind of apotheosis, and who having been already called the son of Jupiter Ammon while living, had been treated as a divinity after his death. He is therefore portrayed as a young Jupiter Ammon. Probably, however, he would not have been able, even when dead, thus to usurp the place of a divinity upon the coins, had not the Greeks become accustomed to the oriental “worship” of the sovereign which he adopted. This innovation rapidly produced a complete change; and every king of the houses which were raised on the ruins of the Greek empire could place his portrait on the money which he issued, and few neglected to do so, while the sovereigns of Egypt and Syria even assumed divine titles.

The reign of Alexander produced another great change in Greek coinage, very different from that we have noticed. He suppressed the local types almost throughout his empire, and compelled the towns to issue his own money, with some slight difference for mutual distinction. His successors followed the same policy; and thus the coins of this period have a new character. The obverses of regal coins with portraits have the head of the sovereign, which in some few instances gives place to that of his own or his country's tutelary divinity; while figures of the latter sort almost exclusively occupy the reverses. Small symbols on the reverses distinguish the towns in this class.

The Græco-Roman coins commence, at different periods, Græco-Roman with the seizure by Rome of the territories of the Greek Roman states. They are almost all copper; and those in that metal coins are the most characteristic and important. In their types we see a further departure from the original religious intention of those of earlier times, in the admission of representations not alone of eminent persons who had received some kind of apotheosis, such as great poets, but also of others, who, although famous, were not, and in some cases probably could not have been, so honoured. We also observe on such of these coins as are Greek imperial many Roman types of an

Greek
Coins.

¹ The head of a river-god, supposed to be the Achelous, is represented on coins of Cēniadēs as that of a bearded man covered with the skin of the head and neck of a bull. Col. Leake (*Numismata Hellenica*, Eur. Greece, pp. 79, 80) notices how this illustrates a passage in the *Trachiniae* of Sophocles, where Dejanira describes the forms under which the Achelous appeared as her suitor.

“Μνηστήρ γὰρ ἦν μοι ποταμῶς, Ἀχελῶν λέγω,
“ὅς μ' ἐν τρισὶν μορφαῖσιν ἐξήτει πατρός,
Φοινῶν ἰνουργὴς ταύρος, ἄλλοτ' αἰδώς
Δράκων ἱλικτὸς, ἄλλοτ' ἀνδρείῳ κύστι
Βούπρωρος· ἐκ δὲ δασκίου γυναικῶς
Κροναὶ διζήρουντο κρηναίου ποταμοῦ.” (9-14.)

The scholiast alludes to a passage in the description of the contest of Achilles with the rivers, in the *Iliad*, where the Scamander throws forth the slain, bellowing like a bull, *μιμνήσκος ἥντι ταύρος* (xxi. 237.) The whole is very illustrative of the feeling which gave rise to the representations of vases and coins. Homer stands before the period of these designs, whereas the tragedians lived long after its commencement. He is original, while they may but reflect in their writings the subjects which they saw everywhere portrayed. It may be observed, that the first and third forms of the Achelous mentioned by Sophocles occur as those of rivers on vases and coins, besides that the third is varied by being represented without a beard, and that the second is found on vases, as that of the Achelous. A bull is the most common symbolical form of a river on the coins.

Greek
Coins.

allegorical character. The following principal kinds of types may be specified, in addition to those of the two previous classes:—

1. Head or figure of a famous personage who either had received a kind of apotheosis, as Homer (Smyrna), or had not been so honoured, as Herodotus (Halicarnassus), and Laïs (Corinth).

2. Pictorial representations, always of a sacred character, although occasionally bordering on caricature. We may instance, as of the latter sort, a very remarkable type representing Pallas playing on the double pipe, and seeing her distorted face reflected in the water, while Marsyas gazes at her from a rock,—a subject illustrating the myth of the invention of that instrument (Apmæa Phrygiæ).

3. Allegorical Roman types, as Hope, &c., on the coins of Alexandria of Egypt, and many other towns. These were of Greek origin, and owed their popularity to the sculpture executed by Greeks under the empire; but the feeling which rendered such subjects prominent was not that of true Greek art, and they are essentially characteristic of the lower school, which attained its best condition at Rome under the early emperors. Of this sort of type we must again speak in noticing the Roman coinage.

Those kinds of types which were common to this and the older classes were also considerably developed in their subjects. Thus, for instance, groups frequently took the place of single figures; and the representations of sacred localities acquired a great prominence—the most common being of buildings, which are generally temples. In the architectural types, a tendency to pictorial representation is evident in the constant endeavours to depict edifices in perspective.

There is a class of coins which is always considered as part of the Greek imperial, or Græco-Roman with imperial effigies, although in many respects distinct. This is the colonial series, struck in Roman coloniæ, and having almost always Latin inscriptions. As, however, these coloniæ were towns in all parts of the empire, from Emerita in Spain (*Merida*) to Niniva Claudiopolis (*Nineveh*) in Assyria, in the midst of a Greek population, and often of Greek origin, their coins help to complete the series of civic money, and, as we might expect, do not very markedly differ from the proper Greek imperial coins, except in having Latin inscriptions, and showing a preference for Roman types.

We have now to speak of the meaning of the inscriptions of Greek coins. These are either principal or secondary; but the former are always intended when inscriptions are mentioned without qualification, since the secondary ones are non-essential. The inscription of civic money is almost always the name of the people by which it was issued, in the genitive plural, as ΑΘΗΝΑΙΩΝ, on coins of the Athenians; ΣΥΡΑΚΟΣΙΩΝ, or coins of the Syracusans. The inscription of regal money is the name or name and title of the sovereign in the genitive, as ΑΛΕΞΑΝΔΡΟΥ, or ΒΑΣΙΛΕΩΣ ΑΛΕΞΑΝΔΡΟΥ, on coins of Alexander the Great. It has been hitherto always supposed that the word understood is "money" (*νέμισμα*); so that the inscriptions were read "money of the Syracusans," "money of Alexander," &c. Mr Burgon has, however, formed a different opinion; and although he has not yet made public the results of his inquiry, he has very generously communicated them to us, with permission to use them, without of course entering into details. He supposes the inscription to relate to the type, and that the word understood is the name of that type. It should be remarked that the type of the reverse of a coin being usually a complement of that of the obverse, there is in general virtually but one type—that of a tutelary divinity of the place or sovereign. The Athenian coins we have mentioned with the inscription ΑΘΗΝΑΙΩΝ have the type of a head of Pallas; and the meaning is therefore, according to Mr Burgon's explanation, not "the money of the Athenians," but "Pallas of the Athenians." When the name of the divinity represented is written, the word understood is supplied. Thus on coins of Syracuse, with the head of Arethusa as the type, we read ΑΡΕΘΟΥΣΑ—ΣΥΡΑΚΟΣΙΩΝ; and on others, with the head of Jupiter, ΖΕΥΣ ΕΛΕΥΘΕΡΙΟΣ—ΣΥΡΑΚΟΣΙΩΝ. We should not be justified in further discussing this explanation; but we must add, that its fitness to all inscriptions, and its congruity with the religious meaning of the types, as first discovered by Mr Burgon, afford the best arguments for its correctness. The secondary inscriptions either describe secondary types, as ΑΘΛΑ, accompanying the representation of the arms given to the victor in the exergues

of Syracusan decadrachms; or are the names of magistrates or other officers; or, in regal coins, those of cities, or those of the engravers of the dies, of whom sometimes two were employed, one for the obverse, and the other for the reverse; or are dates. These inscriptions are often but abbreviations or monograms, especially when they indicate cities on the regal coins.

The importance of Greek coins as illustrating the character Art of of contemporary art cannot be easily overrated. We would coins.

here speak of them in this relation in a general sense, without inquiring as to their bearing on particular branches of art. We would endeavour to assign them their true place as records of art, rather than to discuss their illustration of kindred monuments. It is indeed most desirable that something of this kind should be attempted. The question that is here proposed has not received a proper consideration; and the partialities of a period of bad taste, themselves founded on partly spurious merits, have been handed down as traditions not to be questioned to those who receive with too blind a reverence all the productions of Greek art. Not alone discriminating praise, but the most jealous observation of faults, characterizes the highest kind of regard. All human art must be faulty; and blind admiration indicates nothing better than a weak judgment. The Greek artists, indeed, by making beauty the first quality in art, and by forming a system which, while it forbade extravagance, checked development, committed fewer faults than any others; but they did commit some faults. Notwithstanding the geometrical severity of their temples, the rigid exclusion of historical subjects from their sculpture of the best period, and the tameness of their use of colour in ceramic art, they have been in some things guilty of bad taste. Nothing could be more barbarous than to represent not only a human figure, but that of a woman, sustaining a vast weight, and sustaining it with difficulty. If it be excusable to represent giants thus supporting great masses, can it be to put women in their place as the columns on which a building rests? So, too, in sculpture—in a higher sense, and therefore as deserving far stronger censure—is false taste shown in the exclusion of historical subjects, because they were not capable of ideal treatment. Who can forgive a nation which was content to commemorate the battle of Marathon in a perishable painting, when meaningless combats of Greeks and Amazons, sculptured in enduring marble, adorned the walls of its temples? Great Pericles must be represented in a helmet, because his head was too long to be symmetrical. Thus the Greeks, with their love of material beauty, could not fully perceive the intellectual beauty of truth. In ceramic art, we find even in the best period faulty forms and exaggerated designs. We must the more carefully look for such things since the general excellence and uniformity of Greek high art is apt to deaden the power of discrimination. So long, however, as we know that this was a human art, worked out by human hands, which, like all other art, had its infancy, its manhood, and its decline and death, we know that it cannot have been perfect, and mistrust our judgment if for a time we think it so. Feeling thus, we come to the consideration of any monuments of Greek art, not without earnest admiration and respect for its high beauties and excellencies, yet conscious of its defects and shortcomings; expecting to see in it, as in all human things, the mysteriously-blended good and evil, and carefully maintaining such an independence as may enable us to avoid blind admiration, and such an interest as may preserve us from cold criticism.

Excellence in art is not perceived at the first search, nor does it shine out in the boldest objects. So in nature the highest beauty often demands the greatest toil, and is found at last, not flaunting in the glare of sunlight, but hidden in some untrodden recess. We must not look to size, nor regard boldness, nor think of the value of the material. We must even set aside the mechanical fineness of execution, seeking only that pure excellence that requires no adventitious aid, and is seen, at least in its intention, through a rude exterior. A few lines by the hand of a master have more meaning than the most elaborate work of a copyist. It is also needful carefully to separate the subject from the artistic execution. A fine head will often give a medal a supposititious excellence, while another difficult to treat will produce an equally supposititious badness.

The art of Greek coins, strictly so called, is separated into three great periods—the period of advance, that of excellence, and that of decline. The first period extends from the time

tions.

Greek
Coins.

of the earliest coins to about the commencement of the administration of Pericles, B.C., 440; the second period extends for about a century from this era to the overthrow of Greek liberty, which we may date at the battle of Chæroneia, B.C. 338; and the third period extends downwards to the cessation of the Greek coinage, at the death of Gallienus, A.D. 268. The last age might be held to conclude with the commencement of the Roman empire, since about that time the decline of pure Greek art had been completed, and the later coins are rather to be considered as Græco-Roman in art, as in all else, than Greek. Here, however, we limit ourselves to the works of the second period, that of excellence, to which we have assigned a duration of about a hundred years, from B.C. cir. 440 to 340. These may be considered as extreme limits, since in some Greek cities the coinage did not attain its highest beauty until somewhat after the rise of Pericles to power, and in none, before his time; and in the same manner, the decline appears in some cities to have commenced considerably before the reign of Alexander, but nowhere at a later period. It seems probable, judging from the chronological and historical indications of coins, as well as from the relative number of those of different styles, making, in the latter case, some necessary allowances, that in no city or state did the period of excellence last more than a century, and that its usual duration was from fifty to seventy years.¹

Best
period.

The finest Greek coins may be separated into two great classes, distinguished by a marked difference of style: those struck in Greek cities of Asia, of eastern Europe, and of the islands of the Ægean Sea; and those struck in Italy and Sicily. The former class has far finer designs than the latter, but is frequently deficient in execution, partly, no doubt, on account of its having been issued by less opulent cities. The difference is not unlike that which we observe in ancient and modern gems, although it is not nearly so wide. An ancient gem of good time is characterized by an excellence of design, usually combined with an execution which is, however powerful, poor and rude. A modern gem rarely fails in skillful execution, although its design is generally, in comparison, either tasteless or in bad taste. The coins of Greece Proper and its eastern colonies during the best period, although often indifferently executed, show an unequalled vigour of drawing; while those of the Italian and Sicilian cities display far inferior art, of which the details are worked out in the most elaborate and delicate manner. The obverse-type of a coin of the Greek class looks like the copy of a head from the sculptures of the Parthenon; that of one of the Italian class, like a carefully-wrought gem. The former will bear magnifying rather than the latter, which has, nevertheless, the advantage in the execution of its details. We may thus separate two great schools, which may be compared to those of Phidias and Lysippus, as possessing like them these main characteristics: that the one aimed at reality,—the other at effect; the one at representing things as they are, either in reality or in the imagination,—the other at representing them so as to be seen to the best advantage. While the two schools endeavoured to attain the same result,—a representation of what was most beautiful,—they did so with a very different feeling. The nobler school set before it the perfection of various kinds of beauty, the vigorous as well as the delicate, and thus did not suffer itself to be entangled by that narrow pursuit of one class of objects which infallibly produces mannerism. The inferior school, by requiring all beauty to be soft, and delicate, and rich, fell into the error of neglecting many noble subjects, and soon acquired a mannerism that rapidly destroyed its best elements, so that its decline (as

Greek
Coins.

shown by coins of known date) was far more rapid than that of the other. The difference between the two schools is best perceived when we recollect that the one contains examples of all that is finest in the other, with the addition of many beauties which it does not possess. The Greek school represents, in fact, all high Greek art; while the Italian is but eclectic, and is almost limited to one kind of excellence. We therefore only call the former a school for the sake of clearness.

The coins of the pure Greek school have scarcely been Pure enough studied for us to be able to point to one well-known series as typical of the class. This is, however, partly school. owing to a cause to which allusion has been already made—the fewness of fine coins of this school in comparison to those of the Italian school of the same time, resulting from the relative poverty of the towns by which they were issued. The rude archaic types of the Athenian coinage of the time of the Persian invasion were maintained until art had far declined, probably from commercial reasons;² and the art of the chief trading cities of the west coast of Asia Minor was checked by their conquest or government by the Persians at the time of its excellence. Corinth alone, of the great marts, sent forth a consistently beautiful coinage. The Italian and Sicilian towns, on the other hand, had wealth and leisure enough to carry out efficiently in their coinage their highest idea of beauty. The series which, as a whole, best illustrates the excellencies of the Greek school, is one not deservedly known to numismatists, while it is absolutely unknown to students of art. This is the series of electrum coins of Asia Minor, in so far as it was issued during the period of the best art. The rest of the finest coins of this school are almost exclusively silver; gold or electrum not having been generally common in the Greek cities before Philip's time, and the copper money having been usually neglected. As among the most beautiful Asiatic coins, we must particularize those of Clazomenæ in gold and silver, of the early part of the best period, which bear heads of Apollo, facing, in the boldest and grandest style. In Europe, many of the cities of Macedon, Thrace, and Greece Proper, issued pieces of the highest merit. Nothing in the whole range of Greek art is more beautiful than the head of Apollo in profile on coins of the Chalcidians; nor anything bolder than that of Bacchus in profile on a coin of Thasos, and that of Mercury, facing, on coins of Ænus. In Greece itself, we may notice, as among the finest coins, those of Elis, with the head of Juno, and those of the Locri Opuntii, with that of Proserpine. After a careful review of the best specimens of this school, we perceive that it is identical with the highest school of sculpture, more remarkable for its fidelity, breadth, and boldness, than for its minuteness of execution, and equally happy in purely ideal subjects and in the simple portrayal of natural objects. There are no finer representations of the Greek divinities than those borne by the coins; as a series there are none as fine. Of the portraits the same can be said, but in a lower sense, since there is but one that belongs to the period of the highest art, that of a Persian ruler of Asia Minor, whom there is much reason for supposing to be Cyrus the Younger, on a coin of a Greek mint. The decline of this school was, however, so gradual, that some of the portraits on coins of the earlier part of what we have called the third period, issued in Greece and the East, give an excellent idea of what the best Greek medallic art could have effected in this direction. The representation of natural objects in general is characterized by an equal degree of force and vigour, although there is no attempt to idealize the animals; a lion is a lion, and nothing more.³

¹ It is interesting to compare the duration of the highest Greek art in other branches, and that of other art in different ages. The period of the best Greek sculpture and architecture appears very nearly to correspond to that of the best numismatic art in place and duration, though probably it was a little earlier both in its commencement and its conclusion. The age of the best painting seems to have been even more nearly contemporary with that of the finest coins. The great sculptors and painters after the time of Philip, if we may judge from the copies of their works and the descriptions that are extant, stood very much in the same relation to their predecessors that the later Italian painters did to Raphael. The best Græco-Roman art, in coins as well as in sculpture and architecture, had a longer duration, a circumstance which is explained by its comparative mediocrity; but its utmost limit is less than two hundred years. In more ancient times, the highest Egyptian art in architecture and sculpture is likewise limited to a hundred and fifty years, although its rise and decline were of an extremely gradual character. The great variety of the developments of Christian architecture make it difficult to determine its best periods; but if we separate it into styles, we shall find that the highest excellence of no one much exceeded a century and a half. The same is still more true of the modern schools of painting and sculpture, and of the art of modern coins and medals. If we turn to the East, we observe the same law in the different styles of Mohammedan architecture. The brief duration of the highest art of Greek coins is therefore in no way remarkable; especially when we recollect that its excellence was the result of a very rapid development, and was thus naturally, so to speak, as short-lived as it was extraordinary in its beauty.

² The maintaining of the old Athenian types was probably owing to the reputation of the coins for purity and just weight among the barbarians. For the same reason the Austrian government not long ago re-issued the dollars of Maria Theresa for the trade of the Levant. The Abyssinians in general would lately take no money but one variety of these dollars. (Isenberg's *Amharic Dictionary*, p. 86).

³ It might seem unreasonable to suppose that the lower animals could be treated in art in an ideal manner; but it must be remembered that the

Greek
Coins.
Italian
school.

The most beautiful coins of the Italian school, unlike those just noticed, are well known to every one. They have come to be regarded as examples of the highest Greek medallio art; and hence, perhaps, in some measure the unworthy estimate of that art shown by the neglect with which it is treated. The two most beautiful series are unquestionably those of Tarentum and Syracuse, the wealthiest of the Grecian colonies in the West. Many of the gold coins of both cities belong to the best period of art, and for their rich beauty and exquisite workmanship deserve a high place in the scale of artistic excellence. Their silver coins are still more worthy of careful study, as indicating the growth and decline of art, and as sometimes excelling the gold. The same praise cannot be given to the decadrachms of Syracuse, commonly called the Syracusan medallions. These, though certainly beautiful, display a considerable decline of taste, showing a first development of those faults which amount to caricature in many of the coins of the Carthaginians of which the obverse is similar. Scattered throughout the class there are coins of extreme beauty, especially some of the towns of Heraclea and Thurium in Lucania, perhaps the most vigorous of all in design and treatment; and others of Neapolis, Metapontum, Velia, and Terina, as well as of the Sicilian town of Camarina. These coins, and many others, are undoubtedly extremely beautiful; but as a class they lack the force which characterizes the purer school, and in their rich and profuse detail show a taste which must be pronounced false. We are apt to be dazzled in judging them by the fineness of their metal, the clearness of the execution, the accuracy of the work, and the richness of the designs; but when we come to examine them critically, we look in vain for the bolder excellence of the Greek school; we see not alone very few things that are vigorously treated, but scarcely any that would bear vigorous treatment. Stripped of their ornamentation, many of the designs would be weak, and scarcely any of them, tried by this test, would be for a moment comparable with those of the Greek school.

Modes of
coining.

It is important to study the mode in which Greek money was coined, because the forms of the pieces thus receive explanation, and true coins are discriminated from such modern falsifications as have been struck, and in some degree from those which have been cast. Our direct information on the subject is extremely scanty; but we are enabled by careful inference to obtain a very near approximation to the truth on all the most important points.

It is generally supposed that a certain Roman family coin, issued in the time of Augustus, bears a representation of the instruments of coining. It is a denarius of the family Carisia, and sometimes bears the name of T. Carisius, who was a *triumvir monetalis* of Augustus. On the obverse is the head of Juno Moneta, with sometimes the name MONETA; on the reverse we see an anvil, above which is the cap of Vulcan, bound with a laurel-wreath, while on the right is a hammer, and on the left a pair of tongs. The cap is but little different in form from that which is worn on the head of the bearded Vulcan on the coins of Lipara, and that of the young Vulcan on those of Æsernia; the latter of which has a wreath like the cap of the denarius under discussion. It is also to be noted, that on some coins of Lipara, Vulcan is portrayed holding his hammer in his right hand, and in his left a vessel he has just formed; while on those of Æsernia already mentioned the pair of tongs is placed behind his head as an appropriate symbol. Homer in two passages—the second of which Eckhel quotes—mentions the anvil, tongs, and hammer, as the implements of Vulcan, or of a worker in metal. First in the *Iliad*, when he describes Vulcan making the armour of Achilles, he says—

Ὅππεν ἐν ἀκροθέτῳ μέγαν ἀκμοῖα· γένητο δὲ χειρὶ
Ραιστήρα κραττερὸν, ἐπέφησι δὲ γένητο πυράργηον.
(*Il.* xviii. 476-7.)

In the *Odyssey* the same are mentioned as the special implements of a worker in metal, and therefore, of course, of Vulcan:—

ἦλθε δὲ χαλκεύς,
"Ὅπλ' ἐν χερσὶν ἔχων χαλκὴν ἡία, πείρατα τέχνης,
"Ἀκμοῖά τε, σφύραον τ', εὐποιήτῳ τε πυράργηον,
Ὅϊσιν τε χρυσὸν εἰργάζετο." (*Odys.* iii. 432-435.)

Greek
Coins.

There could be no better description than these two passages afford of the implements represented on the denarius in question: there we see the anvil with the projections by which it would be fitted in the anvil-block, the hammer, and the tongs; nothing is omitted by the poet but the cap, which indeed, stands for Vulcan. With this explanation Eckhel perfectly agrees; but of late it has been usual to consider the type as representing the implements of coining. The cap has been supposed to be a die placed above the anvil, and the hammer and tongs to be here coining instruments. The form of the cap, however, would have been most inconvenient for a die, and the hammer is far better suited for beating out metal than for striking a very heavy blow. Just as the head of Juno Moneta is represented on the obverse because she was held to protect the coinage, so the symbols of Vulcan, the tools of his craft, are placed on the reverse because he was the patron of the workers in metal. We will go further and say, that such an explanation is fully in accordance with the intention which guided the ancient medallists, whereas the other would require a departure from usage.

We are able to describe but a single ancient die of the authenticity of which we are persuaded. Mr Burgon, to whose kindness we are indebted for an account of it, saw it during his residence in the East, but failed to persuade its possessor to part with it. He describes it, from recollection, as a piece of copper or bell-metal, in the shape of a truncated cone, flat at the top and bottom, about $3\frac{1}{2}$ inches in height, and from about 3 inches in diameter at the bottom to 2 at the top. In the upper surface was cut the die for the reverse of a tetradrachm of a Seleucide king of Syria, with the type of Apollo seated on a cortina. There appears to have been no trace of any method of adjusting this to the die of the obverse.

From the appearance which the coins present, it may be inferred that the Greeks placed a ball of metal, carefully adjusted to the proper weight, and cold, between two dies, and then struck the upper die a powerful blow with a very heavy hammer. There was no collar to give the coins an exactly circular form. The dies must have been of hard metal, though less so than modern ones. Some Greek coins have been found of the same die, but such as the writer has seen did not present any evidence as to the wear to which their dies had been subjected. The Roman coins appear to have been struck in the same manner, but with a more careful adjustment of the two sides, yet without a collar. Their dies, although hard, must have been, like the Greek dies, softer than those of the moderns, since, in the case of coins from the same die, we can trace the increase of imperfections through wear, and this notwithstanding the small period for which each die was used, and the relatively few coins struck from it. In the case of Greek coins, there is similar evidence, in the great number which have bad or imperfect impressions, although not worn; since all these can scarcely owe their inferiority to insufficient force having been used in striking them.

Some few Greek and Roman coins were cast and not struck; others, at least in the latter series, were first cast to give them their general form, and then struck. Both cases, however, form very rare exceptions, and are confined to particular groups of coins, and not to isolated examples.

The monetary system of which we propose now to speak is Monetary that of the Greeks and Phœnicians alone. The barbarians system.

who imitated Greek coinage, and whose money is therefore included in the same great class, had also monetary systems, as the general exactness of the weight of the gold and silver coins of any one people at a particular period undoubtedly shows. For the present, however, we must be content to collect evidence as to what these systems were, without attempting to form theories.

The money of the Greek cities, except those of the west of

Greeks idealized the human form, not alone in those expressions which depend upon mind, but in those which are not more than animal. The Egyptians, however, in one particular at least, surpassed them, since they idealized the forms of the lower animals with complete success. The lions in the British Museum, brought by the Duke of Northumberland from Gebel Berkel in Ethiopia, are the best examples of this success in the collections of Europe. They show that the artist has grasped the idea conveyed to him by a lion—conscious strength; and has represented it in a manner which is sublime without being unnatural. No Greek lions are at all to be compared to these.

Greek
Coins.

Asia Minor, which issued electrum coins, appears to have been of silver only from the origin of coinage until after the expedition of Xerxes. Subsequently both gold and copper money was issued. Silver, however, seems to have continued to be the standard, and the gold coins were struck in denominations, usually, if not always, derived from the silver ones. Silver, therefore, is the most important metal.

Silver
money.

The denominations of silver coins were divisions of the mna or mina, which again was a division of the talent. The mina and talent were monies of account as well as weights, and therefore, in discussing the coinage, they may be treated as coins. The only reason that they were not struck must have been their great weight. Although the same system of denominations obtained, with no very great variation, in all the Greek and Phœnician cities, yet there was a relative difference of weight, owing to the use of at least four distinct talents. The ancients mention more talents than these, or else call some of them by more than one name. Mr Burgon, however, after weighing a great number of coins, found no reason to distinguish more than four talents—the Attic, the Æginetan, the Alexandrian or Ptolemaic, and the Tyrian. The Attic talent was used by many Greek cities before Alexander's time, and particularly had no rival in Italy, nor indeed in Sicily, except at two towns for a time at a very early period. Alexander adopted it, and thenceforward it became almost universal in Greek coinage. The weight of its drachm, as deduced from the best evidence, was properly about 67·5 grains troy, and that of its tetradrachm about 270. There was in general no very great depreciation of the Attic weight in subsequent times until the Roman period. The weight of the principal denominations, the drachm and the tetradrachm, we have given to show the relation of the talents. Of the other denominations we shall speak afterwards. The Æginetan talent was as ancient as the Attic, and it is possible that it was even of an earlier origin, most coins of the remotest period being adjusted to it. The Attic talent was, however, the standard of some of the oldest coins, and the instances of the change from the Æginetan to it are not, on the whole, of a character that would warrant the conclusion that it was of later origin. The Æginetan talent is frequent in Greece and the islands in early times. Its drachm weighed about 96 grains, and the didrachm about 192 grains. The Alexandrian or Ptolemaic talent might, Mr Burgon holds, be more properly termed the Macedonian. The first Ptolemy, who was attached to all Macedonian usages, abandoned the Attic weight which Alexander had adopted, and issued money adjusted to the old talent of Macedon. We find this talent to have been that of the earlier coinage of the cities of Macedon and Thrace, and of the Macedonian kings, in both cases before Alexander the Great, and to have been restored, not invented, in the coinage of the kings of Egypt. In the former class, its drachm weighs originally about 58 grains, and its tetradrachm about 232 grains, but they fall gradually to much lower weights. In the latter class, the drachm weighs originally about 55 grains, and the tetradrachm about 220 grains. The Tyrian, which might rather be called the Phœnician talent, was in use among the Persians and Phœnicians. The Carthaginians, however, adopted the Attic talent in Sicily, while still using the Phœnician in Africa, as the kings of Syria struck their general coinage on the former system, but that of their Phœnician cities on the Alexandrian. The drachm of this talent weighed, according to Mr Burgon, between 58 and 59 grains, and the tetradrachm about 235.¹ The earlier Persian coins are of a somewhat heavier weight. The similarity of weight of the Alexandrian and Phœnician talents might suggest a common origin, but it would be hazardous, with the slight evidence we possess, to attempt to form any theory on the subject.

We are best acquainted with the denominations of the coinage of Athens, which followed the Attic talent. These denominations were—the drachm, with its multiples, and its sixth part, the obolus; and that division, with its multiples and its divisions. The following list is drawn out from that in Col. Leake's *Numismata Hellenica* (European Greece, p. 21), where the standard weight of the Attic drachm is assumed to be 67·5 grains:—

1. Δραχμή.....	67·5 grains troy	= 1 drachm.
2. Διδραχμον.....	135·0	" = 2 do.
3. Τετραδραχμον.....	270·0	" = 4 do.
4. Δεκάδραχμον.....	675·0	" = 10 do.
5. Ὀβολός.....	11·25	" = 1/5 of drachm.

6. Τριημιόβολιον.....	16·87 grs. troy	= 1 1/2 obolus.
7. Διωβόλον.....	22·5	" = 2 oboli.
8. Τριωβόλον, or Ἡμιδραχμον	33·75	" = { 3 oboli, or hemidrachm.
9. Τετράβολον.....	45·0	" = 4 oboli.
10. Πεντάβολον.....	56·25	" = 5 do.
11. Τριταρτημόριον, or Τρισημόριον.....	8·43	" = 1/3 of obolus.
12. Ἡμισόβολιον.....	5·62	" = 1/2 do.
13. Τριταρτημόριον, or Ταρσημόριον.....	2·81	" = 1/4 do.

Greek
Coins.

There were 100 drachms in the mna or mina, and 60 minæ in the talent.

In the civic money for which the Attic talent was used the most common piece was either the tetradrachm or the didrachm. Thus, at Athens the great currency was of tetradrachms, at Corinth of didrachms. In the money of the kings the tetradrachm was the chief coin. The smaller pieces were numerous, though fewer than these two most important denominations, except in the lesser cities, which did not frequently strike the latter. A smaller coin that is very frequent in the later period appears to have been an Attic tetrobolon, but was probably also considered to be an Æginetan hemidrachm, since it was introduced not long after the general abandonment of the system of the latter, and when its weight would have been preferred, from its near approach to that of a well-known coin of that system. Those cities which used the Æginetan talent are not known to have issued any larger piece than the didrachm, which is their principal coin. The drachm and hemidrachm are, however, also frequent. In the Alexandrian talent the most common pieces, during the early period, when it should rather be called Macedonian, were the tetradrachm, didrachm, and drachm. At first octodrachms were struck. Under the Ptolemies the common coins were tetradrachms, but decadrachms were also issued. The system of the denominations of the Tyrian or Phœnician talent was somewhat different from that of the other talents, though not essentially so. The principle of division into thirds, seen in the Attic talent in the case of the obolus, which is the sixth part of the drachm, is more fully developed in the Phœnician talent. The Carthaginian coins are principally tetradrachms and didrachms, but dodecadrachms and decadrachms also occur, as well as drachms and smaller pieces. In the cities of Phœnicia tetradrachms were the largest and the most important coins. In the Persian series the principal pieces are tetradrachms and coins of a third of their value, with different types, which are usually called silver Darics. It is probable that this system tended to produce the issue of the pieces called cistophori by the cities of the west of Asia Minor at a late period. These coins must originally have been struck as Attic tridrachms; but they appear afterwards to have been considered to be tetradrachms, and if this be established, they are examples of a fifth system. It is probable that the names of most denominations were the same among the Greeks, and that the Persians and Phœnicians had a different nomenclature, although the Greeks would have called their coins, in so far as they agreed with their own, by Greek appellations.

The gold and electrum coinage appears to have been everywhere based upon the silver in its denominations; for, although money. in many cases it is very difficult to arrive at even a probable conclusion, from the fewness of specimens, all the direct evidence seems to be in favour of this opinion. The oldest coins are the electrum staters of the west of Asia Minor, commonly called in ancient times Cyzicene staters. Their weight is about 248 grains, which is a little in excess of that of the Phœnician tetradrachm. It contains, however, only about 186 grains of pure gold, three-fourths of the whole weight, the remaining fourth being of silver, and as the latter appears not to have been taken into account, the relation seems rather to have been to the Æginetan didrachm. There were smaller denominations, of which one, the hecta, which was the sixth part of the Cyzicene stater, was very common. Other pieces appear to have the weight of the third of the stater. The Persian staters, anciently called Daric staters, and now gold Darics, are of pure gold, and are in weight equivalent to rather light didrachms of the Attic talent. In European Greece there is little gold money before the time of Philip of Macedon. He issued staters of the weight of Attic didrachms. Subsequent kings struck distaters, or gold tetradrachms; hemistaters,

¹ Thomas Catalogue, Greek, &c., Coins, p. 57.

Greek
Coins.

or gold drachms; and smaller coins. The largest known coin of the cities which was struck in gold is the stater, and it is usually less common than lower denominations. The system upon which this coin, which may be considered to be the basis of the gold money, was subdivided, has not yet been fully determined. The Ptolemies struck staters, adjusted to the Alexandrian talent, as well as octodrachms and pentadrachms.

Copper
money.

There are at least two distinct systems of denominations of Greek copper money anterior to the Roman domination, which we may term the Greek and the Italian. Of the former system the principal coin was the chalcus, or piece of brass, of which eight went to the obolus of silver. There was a smaller piece called a leptum, of which the chalcus is said to have contained seven. The coins have usually been so carelessly struck that it is difficult to separate them by weight. The Italian system, which was used in Italy and Sicily, and does not seem to be of foreign origin, is better known. The weight is more accurate, and the value is frequently marked upon the coins. The highest denomination was the as, according to the Roman nomenclature, which was at first, nominally, the pound coined, and was thence called *as libralis*; and the unit was the uncia, or ounce, its twelfth part. The common divisions were the semissis or semis, the half of the as; the triens, or third; the quadrans, or quarter; the sextans, or sixth; and the uncia. Although originally these were coined at near their full weight, they were afterwards rapidly reduced, until at length the as contained but half an ounce of metal.

(The most important works on the entire class of Greek coins may be here mentioned. The account of Greek coins in Eckhel's *Doctrina Numorum Veterum*,¹ will be found to contain the condensed result of the studies of the author's predecessors, with much valuable matter of his own. Although not equal to the part relating to Roman coins, this treatise is of very high merit, and has not yet been superseded. Sestini, in his *Classes Generales*,² has published an excellent companion and supplement to Eckhel. Following that author's arrangement, he has enumerated the principal inscriptions of Greek coins, and has thus afforded great assistance to those who are engaged in their classification. Mionnet's voluminous *Description de Médailles Antiques*, &c.,³ is very useful, but of little authority. It is a catalogue of Greek coins, compiled with much industry by one who had great practical knowledge, but who was not otherwise qualified to attain a high place as a numismatist. Colonel Leake has lately published a catalogue of examples and electrotypes in his possession of coins of the Greek series, excluding most of those struck by barbarians.⁴ The notices given in this work of the geographical, historical, and mythological references of the coins are of high value. The most important work on the weights of Greek coins is Böckh's *Metrolologische Untersuchungen*.⁵)

Greek
coinage of
different
countries.

We may now pass on to notice the Greek coinage of each country, following Eckhel's arrangement.

The series commences with Spain, Gaul, and Britain, three countries of which the money presents a general resemblance, constituting the only great class of barbarous Greek coinage. It must not be supposed that the money of the whole class is of one general character; on the contrary, it has very many divisions, distinguished by marked peculiarities: it has, however, everywhere one characteristic in common,—that its devices are corrupt copies of those of Greek or Roman coins. The earliest of these barbarous coins appear to be the best imitations of the gold and silver money of Philip II., King of Macedon. Next in order of time come the imitations of Roman family coins, the denarii of the commonwealth, in both Spain and Gaul, and that copper money of the former country which followed its silver imitated types. There are in these coinages evident imitations of Greek designs, besides the Macedonian ones we have mentioned, to which it is not easy to assign a chronological place, though they are probably anterior to the imitations of the Roman coins, but not to the more accurate money of Greek colonies, especially Massilia in Gaul. It is useless to attempt a very minute classification of the subjects of these barbarous types, since the artists by whom they were executed did not properly

understand them; and we must be contented if we can perceive the general though accidental principles to which they owe their origin.

Greek
Coins.

The coinage of Hispania or Spain, corresponding to the modern Spain and Portugal, was issued during a period of not more than three hundred years, from about B.C. 250 to A.D. 41. The earliest coins can scarcely be carried further back than B.C. 250, and probably were issued long subsequently; while the latest are of the reign of Caligula, during, or at the close of which, the coinage was evidently stopped. The money of this period was of four classes,—the Celtiberian, or native; that of the Phœnician, and that of the Greek colonies; and the Roman coinage. To the Celtiberian class specimens of the earliest period of Spanish coinage undoubtedly belong; so that its commencement was about, or probably after, B.C. 250. Its cessation must have been caused by the subjugation of Spain to the Roman commonwealth in the middle of the second century B.C. The coins are of silver and copper, no gold pieces being known. In form they are flat, and, in the case of the copper, rather thick. The silver have the general appearance of Roman family denarii, of which, indeed, they are imitations; while the copper again are imitations of the silver. The most common obverse-type of the coins in both metals is the head of a divinity, and the reverse-type a horseman or two horsemen. The inscriptions are in Celtiberian characters, and appear to be always the names of the cities, and perhaps also tribes, by which the coins were issued. The Celtiberian alphabet is manifestly of Phœnician origin; but the language which it was employed to express appears to have been that of the aboriginal inhabitants, represented by the modern Basques. The art of these coins is barbarous. With reference to their denominations, it must be remarked that the most common silver pieces have about the same weight as the Roman denarii of the period, and the Greek-Attic drachms, then nearly equal to the denarii. It is not easy to decide from which of the two it was adopted, but the balance of evidence seems to predominate in favour of a Roman source.

The change from the Celtiberian to the Latin coinage does not seem to have been abrupt. We find certain coins with inscriptions indicating a transition, while in art and types they show a relation to the later Celtiberian pieces, as well as to the earliest Roman. Their inscriptions are either bilingual, in Celtiberian and Latin, or else they are written partly with Celtiberian and partly with Latin characters.

Phœnician and Greek colonies issued money of their own during the period of the Celtiberian coinage. The Phœnician coins, such as those of Gades, have types which are not without meaning, but their execution is very barbarous. The Greek coins, as those of Emporiæ, have types which show a distinct meaning, although they are executed with a coarseness often amounting to barbarism.

The Roman coins of Spain, besides those which bear inscriptions in Latin and Celtiberian, of which we have already spoken, are of two periods,—that of the commonwealth, and that of the empire. The money of the former class differs little in art or intention from the Celtiberian coinage, which it superseded; but that of the latter shows a considerable change in the character of the types. The imperial coins were all issued by Roman colonies. Their art cannot be said to indicate any important progress, but their inscriptions are accurate, and the types display a distinct intention. Their obverses bear the head of the emperor, or of some imperial personage, while the reverses have types usually referring to the foundation of the colonies by which they were issued. Among the most common reverse-types may be specified the emperor or a priest guiding a plough drawn by two oxen, a subject representing the ceremony of describing the extent of the walls; an ox, intended to convey the same idea; an altar, sometimes called in the inscription the altar of Augustus, the founder; and a temple.

The following are the most important coins in the three provinces of Hispania:—In Lusitania we may notice the imperial money of its capital, Augusta Emerita, which took its name from its having been a settlement of pensioners (*emeriti*). The denarii of the legate of Augustus P. Carisius, which bear the name of this place, were perhaps struck at Rome. In Bætica, the series of the Phœnician colony Gades is especially worthy of note; and in Tarraconensis, those of the Greek colonies Emporiæ and Rhoda. The money of the Spanish island of Ebusus is of a remarkably Phœnician character.

(The principal books upon Celtiberian coins are M. de Saulcy's *Essai*,⁶ and two works by M. Boudard,⁷ the second of which, now in

¹ *Doctrina Numorum Veterum* conscripta a Josepho Eckhel, 8 vols. 4to, Vind., 1792–1798.

² *Classes Generales seu Moneta Vetus Urbium Populorum et Regum ordine geographico et chronologico descripta*, editio secunda, 4to, Flor. 1821.

³ *Description de Médailles Antiques Grecques et Romaines avec leur degré de rareté et leur estimation*, par T. E. Mionnet, 6 vols. and 1 vol. plates, 8vo, Paris, 1806–1813; *Supplément*, 9 vols. 8vo, 1819–1837. The terms *Grecques* and *Romaines* are here used for “Greek autonomous” and “Greek imperial.” The indexes in the ninth volume of the *Supplément* are especially useful.

⁴ *Numismata Hellenica, a Catalogue of Greek Coins collected by W. M. Leake*, 4to, London, 1854.

⁵ *Metrolologische Untersuchungen über Gewichte, Münzfüsse, und Masse des Alterthums*, &c., von August Böckh, 8vo, Berl. 1838. It is unfortunate that this learned author was not so fully acquainted with the numismatic as with the literary materials for his subject. From the researches of Don V. Vazquez de Quesipo much information may be expected. The writer is indebted to him for much liberal assistance.

Greek
Coins.
Gaul.

progress of publication, promises to be a very complete treatise. There is also an excellent sale-catalogue, by M. Gaillard, of a large collection of Spanish coins, and coins current in Spain in ancient and modern times, formed by Don Garcia de la Torre.¹)

The coinage commonly called that of Gaul should rather be classed to the Gauls, since it belongs to the people more properly than to the country; for, in addition to the money struck in the territory called after them, it comprehends pieces issued by the Gauls or other barbarians near Macedonia and Illyricum, and in the south of Germany. The Gaulish coinage appears to have generally extended over a period of less than four centuries; for the oldest pieces, as far as we can ascertain, are those which follow the types of Philip II. of Macedon, and the latest are the Roman of Augustus.² Some of the Greek coins of Massilia may be of a time somewhat anterior to that of Philip. There are two principal classes,—the true Gaulish coinage, and that of Gaul under the Romans.

The ancient Gaulish coins are of gold (often greatly alloyed with silver or copper), of silver, of copper, and of potin. They are usually convex, and, in the case of the gold and potin, generally thick and heavy. The earlier designs are copied from those of Greek money, the gold and silver coins being imitations of the staters and tetradrachms of Philip II. of Macedon. At a later time the silver and copper coins of the Gaulish chiefs and tribes chiefly follow the designs of Roman denarii of the commonwealth and the beginning of the empire. The early class is uninscribed, except when part or whole of the Greek legend is imitated; but the later class bears Latin inscriptions. The art of both is barbarous, although that of the later class is better than that of the earlier in this respect. There appear to be two monetary systems, but they are not clearly made out; although it is most reasonable to consider them to have been imitations, the one of the Macedonian system, and the other of the Roman.

The money of the important Greek colony of Massilia forms a separate class with that of the far less noted towns of Antipolis and Beterra, in the same division of Gaul. It was issued during at least three full centuries preceding the subjugation of the country by the Romans. Its metals are silver and copper, gold coins not having been discovered. The designs and inscriptions are purely Greek, and the art, in the case of Massilia, is not unworthy of an isolated colony. The denominations appear to follow the Attic talent.

The proper Roman coinage of Gaul is, as far as is known, of copper only, although there is silver as well as copper money of some reguli protected by the Romans before the complete reduction of the country. This Roman money is of a few coloniae alone. Like the contemporary Spanish pieces of the same class, the coins are large and coarsely executed. On the obverses there are commonly two heads,—either those of Augustus and Julius, or Augustus and Agrippa, back to back. The designs of the reverses appear usually to relate directly or indirectly to the establishment of the coloniae. The inscriptions are in Latin, and the denominations seem to follow the Roman system.

Some of the more important or interesting coins may be now indicated in the order of their proper arrangement. Here we deviate from the principles of those continental numismatists who comprehend all the coins of Britain under Gaul. While admitting the common general character of the money of the two countries, and that some coins virtually identical may have been struck on both sides of the Channel, we perceive a sufficient difference in the majority of specimens found in England and on the Continent to render a distinction necessary. Besides this, many of the coins found in our own country bear names which are undoubtedly those of British towns or chiefs, such as Verulamium and Cunobelinus. It is not easy to define in a few words the main particulars in which early Gaulish and British coins differ; but it may be said that the former are generally in a style either somewhat better or much worse, especially in the quality of grotesqueness, than that of the latter. Passing by Gallia Aquitania, as numismatically uninteresting, we may notice in Gallia Narbonensis the coins of the Greek city of Massilia, some of which, in the silver series, are of great beauty, although the larger proportion are below the average of Greek money of the period in their art. The Roman coloniae Nemausus and Vienna,

in the same division of Gaul, are represented by copper coins of some interest. Those of the former place have for their type of reverse a crocodile chained to a palm tree, in commemoration of the subjugation of Egypt by Julius or Augustus, and those of the latter bear the device of a galley passing a castle. Among the towns of Gallia Lugdunensis, Lugdunum (called on the coins of the empire *Copia*) may be pointed out for its autonomous and imperial money. Besides these coins of cities, there are many having the names of Gaulish chiefs and tribes. Some of these are classed with the cities, because the position of the territories they ruled or occupied in one of the great divisions of Gaul is known; but others cannot be so placed, and are therefore arranged alphabetically, after the geographical series. Among the last are many uncertain names, which may be of towns, tribes, or chiefs. Especial caution is needed in any attempts to find the historical places of Gaulish chiefs. The information to be derived from their coins is so meagre that there is great danger of mistake in such endeavours. If, for example, the name of a chief is read, and the position of his territories ascertained, it does not follow that he is identical with one bearing the same name, and holding the same territories, mentioned by an ancient author; yet the contrary supposition is not unnatural. At the end of the Gaulish series are placed the uninscribed coins, some of which are among the earliest pieces issued by the Gauls, while others are probably of various times in the subsequent periods of their native coinage until its very conclusion.

(The principal works upon the coins of Gaul and the Gauls are,—the learned treatise of M. Lelewel;³ the accurate *catalogue raisonné* of Gaulish coins in the French Collection, by M. Duchalais;⁴ the account of the money of Gallia Narbonensis, by M. de la Saussaye;⁵ the essay on that of the north-west of France, by M. Lambert;⁶ and the papers of the Marquis de Lagoy on various Gaulish coins.⁷)

The ancient coinage of Britain is of the period before the complete subjugation of the country by the Romans. It is manifest that it was derived from that of Gaul, but it is not possible to say how long after the origin of the latter. There are no coins of which we know the date until the time of the struggle with the Romans. Taking into consideration the general persistence of the types, and the regularity of the weight and fabric, of the whole gold coinage, it is most reasonable to suppose that it was issued during a period of about two centuries, closing cir. A.D. 43. It would therefore appear that the Britons had a metal currency at the time of Caesar's invasion. The received text of Caesar's *Commentaries*, indeed, states the very contrary; but Mr Hawkins has shown that the manuscripts, however they differ in the passage in question,⁸ agree in relating that the use of either gold or copper money obtained among the Britons, and has traced the existing corruption to the editors of the middle of the seventeenth century. He cites a manuscript of about the tenth century, in the British Museum, which reads as follows:—"Utuntur aut ære aut nummo aureo aut annulis ferreis ad certum pondus examinatis pro nummo;" a statement, as far as the money is concerned, entirely confirmed by numismatic evidence.⁹ The silver coinage, it must be observed, is not known to have been issued until after Cæsar's time, no specimens which can be considered to be much anterior to Cunobelinus, who is believed to have been contemporary with Augustus, Tiberius, and Caligula, having been found. British coins are properly of but one class, since there is no money but that of the natives. The metals used are gold, silver, copper, and potin. The coins greatly resemble those of Gaul in form and general appearance, as already noticed. They are thick and convex, the gold being the most remarkable for their thickness. The types of the gold coins are taken from those of the Gaulish in the same metal; the obverses bearing some device based on a degraded form of the head of Hercules on the money of Philip II., which has become a pattern, or even an ear of corn; while the reverses have a horse, with a wheel or other symbols, standing in like manner for the chariot on the Macedonian pieces. The inscriptions are always in Latin. The art of the coins is barbarous, though it often displays a kind of conventional neatness of execution. The monetary system appears to be the same as that of the earlier native Gaulish money.

In arranging the British series, we place first coins bearing the names of known princes or towns; then those bearing unknown

² Strabo (lib. iv., cap. iii.), as Eckhel notices (*Doct. Num.*, vol. i., p. 65), speaking of his own time,—that is, of about the close of the reign of Augustus and the beginning of that of Tiberius,—mentions the striking of gold and silver money by the Roman prefects of Lugdunum. No coins, however, have been found which have the head of any one later than Augustus; and the known Roman imperial money of Gaul is of copper alone.

Greek
Coins.

names; and last, those which are uninscribed. Coins in the second division may be constantly transferred to the first by the careful observation of the places of their finding. The coins of the third division are probably the oldest. They occupy in type a middle place between the coins of Gaul of the same kind and the earliest inscribed British coins of which the date is known, and which are of about the time of Julius Cæsar or Augustus. There are no inscribed coins which can be referred with certainty to any chief mentioned by Cæsar. The earliest of known date are of Tasciovanus or Tasciovans, the father of Cunobelinus. He must have reigned about the time of Augustus, for we cannot place him earlier, since one of his silver coins shows a manifest imitation of a type of denarii of that emperor in its obverse and reverse; nor can we suppose his reign to have extended much later, since he was the grandfather of the famous Caractacus. The coins of Cunobelinus, the son of Tasciovanus, and Shakspeare's Cymbeline, are the most interesting in the British series. He is supposed to have been a contemporary of Augustus, Tiberius, and Caligula, an opinion which cannot be far wrong, since he was the father of Caractacus, and to have ruled over a territory extending from the Severn to the east coast, and comprising the country of the Cateuchlani, Trinobantes, and Dobuni.¹ His coins are of gold, silver, and copper; the gold pieces following the old barbarous types, with some improvement in execution; and the silver and copper having types derived from those of Roman coins, or at least showing Roman influence. They have the names of the king and his father, both generally abbreviated, and sometimes those of two towns where they were struck,—Camulodunum, his capital, probably represented by Maldon in Essex, and Verulamium or Verulam. There are coins bearing the inscriptions SEGO and TASC, which have been ascribed to the Segonax mentioned by Cæsar;² but Mr Evans assigns them, with more reason, to the tribe of the Segontiaci. This tribe he supposes to have been ruled by a chief called Epaticcus, known only by his coins, whom he conjectures to have been a son of Tasciovanus, and on his death to have shared his kingdom with Cunobelinus. Other coins have been ascribed to Boadicea, because they bear the inscription BODVO; but this must be considered to be a purely conjectural attribution.

(There is no general account of British coins which can be called complete. This is partly owing to the circumstance that their proper explanation has been the result of recent inquiries; but it is to be hoped that this deficiency will soon be supplied. The works of Ruding³ and Hawkins⁴ give a concise notice of these coins; there is an essay on those of Cunobelinus by the Marquis De Lagoy;⁵ and the *Numismatic Chronicle* contains several most important papers on British money by Mr Evans.⁶)

Italy.

The ancient coins of Italy occupy the next place in Eckhel's arrangement. They appear to have been struck during a period of more than 500 years, the oldest being probably of the beginning of the sixth century B.C., and the latest somewhat anterior to the time of Julius Cæsar. The larger number, however, are of the age before the great extension of Roman power, which soon led to the use of Roman money almost throughout Italy. There are two great classes, which may be called the proper Italian and the Græco-Italian; but many coins cannot be referred to either, since they present peculiarities of both. The proper Italian coins are of gold, silver, and copper. Of these, the gold coins are extremely rare, and can never have been struck in any large numbers. The silver are comparatively common, but the copper are very numerous and characteristic. Some of the silver coins have an incuse device on the reverse, which almost always is a repetition of that on the obverse: these are of Greek cities, but their fabric is nearly peculiar to Italy. There are also a few with a design on the obverse and a perfectly plain reverse. The most remarkable copper coins of this class are of the kind now called *as grave*, some of which must be considered to be the early proper coinage of Rome, although

others are known to have been struck by other Italian cities. These are very thick coins, some of which are of great size, while more have a rude appearance. The designs of the Italian coins are generally, if not always, of Greek origin, although the influence of the native mythology may be sometimes traced. The inscriptions are in Latin or Oscan, and follow a native orthography: sometimes on the earlier coins they are retrograde. The art of this class is generally poor, or even barbarous. The denominations appear to be Greek, except in the case of the copper money, which follows a native system. Of this system, which we have already noticed, the early proper Roman coins afford the best known examples. The Græco-Italian coins are of gold, silver, and copper. The silver and copper are very common, and the gold comparatively so, although struck by few states or cities. In form the silver and copper coins are thicker than those of Greece of the same period, but there is not the same difference in the gold. The designs are of Greek origin, although here, as in the proper Italian coins, but less markedly, can native influence be detected. This influence is evident in the frequent occurrence of types symbolically representing rivers, showing a bias towards the old nature-worship; and still more in the use of Latin inscriptions, with half-Etruscan forms of the letters on coins otherwise purely Greek. Of the best art of ancient Italian money we have already spoken, and we shall have occasion to mention some of its most beautiful examples. The denominations of the gold coins are unquestionably derived from those of Greece, according to the weight of the Attic talent, the heaviest being a stater of that talent. The lower denominations require to be carefully studied before they can be satisfactorily explained. The silver denominations are perfectly Greek, and follow the Attic talent: there are few tetradrachms, the didrachms are extremely common, and smaller denominations are usually not rare. We thus learn that the silver currency was chiefly of didrachms, smaller pieces being less used, and larger ones scarcely used at all.⁷

Commencing in the north of Italy, the first coins that strike us are those of Populonia in Etruria. The silver money of this place is especially remarkable for being generally of a peculiar fabric, already noticed, in which the reverse is left perfectly plain. In Umbria we may notice the *as grave* of Tuder, and in Picenum that of Asculum and Hadria together,⁸ and that of Hadria alone. In Latium would be placed the early coinage of Rome, were it not included in the separate class of Roman money, with the exception of the pieces issued by the Campanian towns with the name of the city. In the province of Samnium we observe a very remarkable series of coins issued during the Social or Marsic War by the Italian states confederate against Rome. They rose to obtain the rights of Roman citizenship, but their league was gradually broken by the conclusion of separate treaties by the senate with individual states. The earliest common reverse-type of their coins represents eight persons, who are probably delegates of the eight states which composed the original league, and certainly stand for those states, taking an oath over a sacrificial pig. The series, as it continues, commemorates the gradual violation of this engagement. The eight persons are reduced to six, the six to four, and the four to two. That these changes should be represented is the more remarkable, if we recollect that the war lasted but three years, from B.C. 90 to 88 inclusive. Some of the coins have Oscan, and others Latin, inscriptions.

In the money of Campania we observe fine Greek work, combined, in some cases, with inscriptions showing an Italian orthography and form of letters. The coins of Cales afford examples of good art in both silver and copper; their inscription is CALENO, apparently a genitive plural form. Those of Cumæ are generally of coarse design and execution; among them are some of an early time. The money of Hyria comprises didrachms of good work of the best period of art, and bearing very archaic retrograde inscriptions, as ANIYY. Neapolis, the modern Naples, is represented by an extensive series, including fine silver coins, particularly di-

Greek
Coins.

⁵ We may hence infer the wealth of the population of Italy before the Roman domination, and the consequent high price of the necessaries of life. In Greece, on the other hand, except at the great towns, such as Corinth and Athens, we notice that the current money is in most places mainly of small denominations. The regal coinages are of course exceptions to this rule. The inhabitants of Greece were, however, less attentive to their copper coinage than those of Italy and Sicily, which may partly explain their having struck very small silver coins. The Athenians had no copper coinage, or one of a merely arbitrary value, when they issued a large number of the low denominations of silver money; but after they had struck copper coins of a real value, their smallest silver pieces were coined in a much less quantity.

⁶ When the names or symbols of two or more towns appear on a coin, it is understood to commemorate an alliance, called on the Greek imperial money, *Opómuu*.

Coins.
Italy.

drachms, and copper coins as excellent in design, and usually coated with the beautiful blue or green *patina* produced by the soil of the neighbourhood. The coinage of the great Greek cities of Italy may be considered to begin with Neapolis, though that of the Italian cities does not here cease. In Numismatics it is impossible to separate money according to a strictly geographical or historical order.—The earliest coins sanctioned by the Roman state are classed as uncertain coins of Campania. Of these we shall speak in treating of Roman money, since to it they historically belong, although most of them are purely Greek in their art, and they are all rightly considered to be of the Greek class. In Calabria, Tarentum affords the largest series of any city of Italy, and one which is, for extent and beauty combined, second alone to that of Syracuse in all the West. The gold coins are extremely fine, and those of silver, which are principally didrachms, are interesting on account of the early style of some, and the exquisite work of others, the latter being of the best period. The usual types of the didrachms are, on the obverse Taras, son of Neptune and founder of the city, carried by a dolphin, and on the reverse a horseman, who, as we shall show in speaking of the coins of Sicily, appears to represent a victor in the horse-race at the Olympic games. The copper coins are few, and not remarkable. The money of the cities of Lucania is very interesting. Among the coins of Heraclea are didrachms of exquisite work, having on the obverse a head of Pallas, with the monster Scylla on the helmet, and on the reverse Hercules strangling the Nemean lion, a design of great vigour, and showing perfect anatomical knowledge. The series of Metapontum, or, to follow the Greek orthography, Metapontium, stands next in its silver to that of Tarentum in extent, and is as beautiful in its finest coins, the subjects of which are even better adapted for that delicate treatment in which the Italian and Sicilian artists especially excelled. The great majority of these coins are didrachms, although the tetradrachm has been discovered. They commence at an early time with didrachms of a class that we have already mentioned as almost peculiar to Italy. The type of the obverse, an ear of bearded wheat, as a symbol of Proserpine, is repeated on the reverse, but is there incuse instead of being in relief. The didrachms of the best period have on the obverse the head of Proserpine, or that of some other divinity, and on the reverse the ear of bearded wheat. Some of these are of extreme beauty. Of Posidonia, afterwards called Paestum, there are archaic coins of the incuse class just mentioned, with the type of Neptune striking with his trident. The famous Sybaris, afterwards called Thurium, is represented, under its first name, by early didrachms with incuse reverses, probably of the sixth century B.C.; and, under its second name, by a very fine series of silver coins of about 400 B.C. Sybaris having been twice overthrown by the Crotonians, the new city Thurium was founded in its stead by a colony from Athens, B.C. 444. The later coins are chiefly didrachms, but there are not a few tetradrachms. Examples of both denominations are of very fine work. Some of the tetradrachms are superior in the quality of boldness, which is rare in Italy and Sicily, and equal in execution to any other coins of those countries. They are nearest, though yet inferior, to the finest coins of Greece and Asia. On the obverse they have the head of Pallas, with Scylla on the helmet, and on the reverse a bull butting.¹ Among the coins of Velia, which are principally didrachms, we notice many of beautiful work. Their common reverse-type, a lion seizing a stag, carries us to Asia, and reminds us that this town owed its origin to a colony of the Phocæans of Ionia, whose native place was taken by the Persians. This and similar types are almost wholly found on Asiatic coins, particularly those issued under Persian rule. They are evidently adopted from eastern symbolism, but with a change of meaning: the original signification seems to have been the strength of regal power, the later one, the strength of a divinity, probably always Hercules. It should be remembered that the difference of feeling among the easterns and the Greeks as to the kingly dignity would render a change necessary to preserve the religious meaning of these types. Passing on to the province of the Bruttii, we observe the coinage of that people, or of the province in general, to be fine in the three

Greek
Coins.
Italy.

metals, though not of the best Italian style, the earliest pieces being probably not anterior to the time of Pyrrhus, King of Epirus. The money of Caulonia comprises early didrachms of the incuse class, with a type not yet satisfactorily explained, representing some divinity. The town of Croton is represented by a series of much interest. It commences with incuse didrachms of an early period. Some didrachms and smaller coins of a time somewhat later are remarkable for having on the reverse, instead of a repetition of the tripod, which is the type of the obverse, an incuse flying eagle. The didrachms of the period of good art are extremely beautiful. Two of their types are of especial interest; one represents Belerophon on Pegasus, slaying the Chimæra; and the other portrays, on either side of the tripod, which is the most common type of the place, Apollo drawing his bow, and the serpent Python which he is about to destroy. The coin last mentioned exhibits very admirable work. The money of the Locri Epizephyrii is fine, but not of an early period: it probably commences just after the time of Pyrrhus. The town of Pandosia is represented by rare silver coins of great beauty. The series of Rhegium comprehends archaic tetradrachms, and others, as well as didrachms and copper pieces, of the best time, and of fine design and execution. The most interesting of these coins are some of the earliest. They are tetradrachms, having on the obverse a victor in a biga, and on the reverse a hare running. This is the type of tetradrachms of Messana of the same period so similar in work to these that they can only be distinguished from them with certainty by their inscription. The type ceases at Rhegium, but continues at Messana, and we perceive by the later coins of that place that the chariot is undoubtedly one drawn by two mules (*ἀρῆνη*).² Aristotle, cited by Pollux, relates that Anaxilaus of Rhegium, having introduced hares into Sicily, and having conquered in the chariot-race of mules at the Olympic games, placed on the money of the people of Rhegium a mule-chariot and a hare.³ The types relating to victories in chariot-races always refer to the success at the Olympic games of a citizen or tyrant of the place which struck the coin, as we shall be able to show. The pieces of Rhegium and Messana in question can only relate to a contest during the period at which the chariot-race of mules prevailed, that is, during the years from B.C. 500 to 448, inclusive. The earlier coins of Messana, and all of Rhegium of this type, must also be of a time when the two towns were under a united government. In the case of Messana, the coins follow a Samian influence, if not domination, since there is a piece of that town with the Samian types, which immediately precedes them.⁴ These particulars all point to the time of Anaxilaus, tyrant of Rhegium, who first invited the Samians perfidiously to seize Messana, then called Zancle, about B.C. 494, and afterwards expelled them, and ruled the two cities until his death. His reign, reckoned from his accession at Rhegium, probably lasted from B.C. 494 to 476. This period corresponds to the style of the coins, which would point of itself to the earliest part of the fifth century B.C.⁵ We may therefore consider that these coins of Rhegium, and the coins of Messana of the same time, bearing the same types, were issued by Anaxilaus after his victory at the Olympic games, of which Simonides sang the triumphal ode.⁶ While we accept the explanation which Aristotle gives of the chariot, we cannot take that of the hare, since there is nothing the least resembling it in Greek numismatics. We would rather consider the latter type to be a relic of the old nature-worship, which was especially prevalent in Italy and Sicily, but of which the Greeks in Aristotle's time had but an indistinct knowledge. We will conclude this notice of ancient coins of Italy with those of Terina, of which the didrachms are of extreme beauty and delicacy. On the obverse they bear the head of a female divinity, called on a copper piece of the same place Pandina; and on the reverse, the figure of a local genius, or of the same divinity, usually, but not always, winged. In one case, the figure is represented filling a jar at a fountain issuing from a lion's head in a wall, and in another, resting seated on a jar, from which flows water; and it is worthy of note that, in the latter type, a flower springs up near the mouth of the jar. Pandina (*Πανδῖνα*) is probably a name of Hecate.

¹ It has been suggested that the name Thurium, "impetuous" or "warlike," might be indicated by the bull, as a speaking type; but it is far more consistent with correct criticism to suppose that the latter refers to the rushing forth of a fountain, or rapid course of a river; a river, as we have seen is frequently represented as a bull, and a fountain might be with equal appropriateness.

² The ἀρῆνη of the Olympic games was a chariot drawn by mules.

³ Ἀναξίλαος ὁ Ῥηγίνιος, αὐτὸς ἀγόνου τῆς Σικελίας πῶς λαγῶν, ὃ δὲ, εἰσαγωγὸν τε καὶ θρέψας, ἡμεῖς δὲ καὶ Ὀλύμπια νικήσας ἀρῆνη, τῷ νομίματι τῶν Ῥηγίνων ἐνέστυψεν ἀρῆνην καὶ λαγόν. (Aristot. ap. Poll., v. 75.)

⁴ There are also coins of Rhegium with the Samian types, which were probably struck at the same period; whence it is reasonable to suppose that some of the Samians settled at Rhegium at the time of the taking of Zancle.

⁵ The Syracusan decadrachms, called *damaretia*, which were struck in one of the three years B.C. 480–478, are certainly of better art than these coins of Rhegium and Messana; but this might be owing to the wealth and importance of Syracuse.

⁶ Millingen's excellent paper "On the Date of some of the Coins of Zancle or Messana," in the *Transactions of the R. Soc. Lit.*, vol. i., part ii., p. 93 et seq., is here our chief authority.

Greek
Coins.

Sicily.

(The most useful works on ancient Italian coins are Carelli's plates,¹ the account of the *Æs Grave* of the Kircherian Museum by MM. Marchi and Tessieri,² and Millingen's *Considerations*.³)

The coins of Sicily properly follow those of Italy. They appear to have been issued during a period of about six centuries or a little more. The oldest cannot be carried further back than the commencement of the sixth century B.C., and the latest are Roman colonial pieces of the reign of Tiberius. The earliest coins are silver; the gold money commences with the period of the best art in Sicily, but is not common during the earlier part of that time; and the copper coinage probably begins during the fifth century B.C. The gold and the silver money cease at the subjugation of the island to Rome; but the copper continues later, some having been issued under the Romans. The latest coins are Greek imperial of Segesta and Roman colonial of Agrigentum, struck in each case under Augustus, and Roman colonial of Panormus, struck under Tiberius. In form the silver and copper pieces are compact and thick.

The types of Sicilian coins most resemble those of coins of Italy, especially of the south. They show the same partiality for representations of rivers, which are not unfrequently accompanied by their names. The most common and important device on the coins of the great towns, usually occurring on the reverse, and sometimes on the obverse, of the larger silver pieces, decadrachms of Syracuse, and tetradrachms and didrachms of that and other places, and on the reverse of some of the gold coins of Syracuse and its kings, represents a victor in a chariot-race. Its exact meaning never having been properly determined, we must give some space to its consideration. The same device, and others that belong to its class, occur on coins of cities out of Sicily; but as they are not so closely related to the Sicilian representation as the various types of that representation are to one another, we will not at present notice them. This device is found on coins of the Sicilian cities of Agrigentum, Camarina, Catana, Gela, Himera, Leontini, Messana, as well as Rhegium in Italy, with the same types as Messana, Segesta, Selinus, and Syracuse, and on coins of kings of the last town. The earliest and latest of these, of which the dates are most nearly known, were struck respectively in one of the years B.C. 480-478, and during the reign of Hiero II., King of Syracuse, B.C. 275-216. There are several types, which are of two classes. The first and more ancient class comprises all the early coins with this device, and closes at the commencement of the period of the best art, about B.C. 430; it is distinguished by the victor being a man. The second class extends through the periods of the best art, and of decline, to the time of the latest coin with the device; in it the victor is a goddess, and latterly usually Victory. On coins of one city, Selinus, of both classes, Apollo and Diana are represented together in the car; in the older ones Diana drives, in the later Apollo; and on tetradrachms of one type of Syracuse, a winged male genius acts as charioteer. The oldest coins of the first class generally have the type of a chariot drawn by two horses; others have a chariot drawn by two mules; and there are also trigæ and quadrigæ of horses. The later coins of the same class have almost always a quadriga of horses. On the earlier pieces the beasts are usually represented in slow action, probably through the unskilfulness of the artists; but on the later ones they are generally in rapid course. One of the *metæ* (*vûremi*) is sometimes seen beyond the chariot, showing that the critical time of the race is intended, when the driver had to avoid disaster by the adroitness with which he turned.⁴ Victory hovers above, with a wreath, about to crown the charioteer, or as if intending to crown the horses. Beneath, in the exergue, on the later coins, we notice symbols, usually dolphins or other marine animals, or objects proper to the sea. On the coins of the second class, the chariot is always a quadriga, either in rapid course, or proceeding slowly as if in triumph. The place of the charioteer is taken by a goddess, as already mentioned, who is either a divinity of the place, as Proserpine at Syracuse and Segesta, and Minerva at Camarina, or Victory; and, except in the last case, Victory hovers above with a wreath, about to crown the victor. As we have already mentioned, on coins of Selinus, Apollo and Diana are represented in the car together, the former driving on those of this class; and on coins of Syracuse, a winged male genius is charioteer: these are exceptional examples. In the exergue are either marine objects or prizes, but not the wreath, with sometimes at Syracuse the inscription *ΑΕΑΑ*, leaving no doubt as to their meaning. These prizes are a suit of armour on coins of Syracuse, and two jars on those of Camarina.

These types plainly refer to victories in the chariot-races of public

Greek
Coins.

Sicily.

games which had reflected honour upon the great towns of Sicily. From the marine symbols, we should infer that they were celebrated on the sea-shore, or were in some manner connected with the sea. The religious character of the types of Greek coins shows that these must have been sacred games; and the substitution of divinities for the charioteers proves that they were held in the highest reverence. In the *Iliad*, when the divinities personally assist the heroes, as especially where Minerva acts as charioteer to Diomed, it is only on some occasion of the greatest importance, in accordance with the Horatian maxim. Usually they aid their favourites less directly, as at the games at the funeral of Patroclus, where the poet makes Eumelus about to succeed through the help of Apollo, until Minerva secures the victory for Diomed. In both cases the idea is the same as that intended to be conveyed by the later types of the coins. It might be contended that games held in such high honour could scarcely have been local celebrations at the towns on the money of which they are commemorated; but there is direct evidence to show that they were not such. One of the *metæ* is represented on coins of Catana, of about B.C. 380, and on others of Gela, of about fifty years earlier, and is in each case an Ionic column,⁵ although the treatment of the chariot and the general style is far different. The types, therefore, refer to chariot-races of four different kinds, celebrated at games held in the highest reverence. To no games will these particulars so well apply as to the Olympic. They were the most revered and famous of all the Greek games, being the chief of the four called sacred; and at them, during the periods at which the various types first occur, were held races of the very four kinds which they represent, the chariot-race of mules having lasted, as previously noticed, only fifty-three years, a period including that during which the first coin relating to such a contest was struck. A victory at the Olympic games was held to be no less glorious to the city of the victor than to himself. It is probable, indeed, that the highest honours were paid to the victor in the foot-race, after whom the Olympiad was distinguished; but there is no doubt that success in other contests, and especially in the chariot-race, was considered as not much less glorious. Nothing, therefore, could be more proper than the commemoration on coins of victories in the Olympic chariot-race; and we have only to inquire whether the cities of Sicily with types relating to such races were successfully engaged in that contest. The remaining odes of Pindar, which are of the very period of the earlier of the coins we are considering, give no doubtful answer. Fourteen of these odes relate to the Olympic games, and of these, again, six celebrate success in chariot-races, every one of which was gained by a Sicilian,—two by an Agrigentine, two by a Camarinæan, and two by Syracusans,—all of cities which struck coins with the chariot-type. If we look at the lists which have been made of victors in the Olympic games mentioned by ancient writers, we perceive that not only these cities, but others of Sicily of which the coins have chariot-types, were successful in the Olympic chariot-race or at other contests of those games.

If any doubt remained as to the correctness of this explanation, it would be removed by the direct statement of Aristotle, already noticed, that Anaxilaus, tyrant of Rhegium, placed the type of a mule-chariot on the coins of that place when he had been victorious at the Olympic games; and that of Plutarch, that Philip II. of Macedon commemorated his success in the Olympic chariot-race by placing the representation of a chariot on his money. The former story we have seen to be confirmed by coins of Rhegium and Messana, and the latter is shown to be correct by the representation, on the reverse of Philip's gold pieces, or staters, of a victorious biga, a type not seen on the coins of earlier kings of Macedon.

This explanation of the chariot-type in the case of Philip's staters leads us to the discovery of the true meaning of a kindred device, occurring on his coins and those of several Greek cities. Philip is also related to have gained the prize in the horse-race at the Olympic games; and, accordingly, the common reverse-type of his largest silver coins, which are tetradrachms, represents a horseman holding a palm. The palm is not the only indication that a race is here referred to; for if we compare this type with the less common one representing a mounted traveller, probably some hero, we observe that the rider in the former case is smaller than in the latter, and the horse perhaps larger. There can, therefore, be no doubt that Philip commemorated his victory in the horse-race, as he did that in the chariot-race, on his coins. This result leads us to examine the common reverse-device of the didrachms of Tarentum, which represents a horseman, naked or armed, generally either crowned or about to be crowned with a wreath by Victory, flying above him, or crowning himself, or crowning his horse.

⁴ *Soph.*, *Electr.* 720-722 and 743-748. The whole of this description, the *locus classicus* on the Greek chariot-races, deserves careful study in connection with the coins, although it must be remembered that it relates to the Pythian games. *Comp. Hor. Carm.*, lib. i., od. i. 3-6.

⁵ It would seem, from the description of Sophocles (*Electr.*, loc. cit.), that the *metæ* at the Pythian games were objects like posts, perhaps columns.

Greek
Coins.
Sicily.

The importance of the horse is shown not alone by his being crowned by the rider; in another type he is embraced, or at least welcomed, by Victory standing to receive him, as if after a race; and again, in another, a small figure, apparently a genius, raises one of his fore-feet and examines the hoof, as if to extract a stone. Another type shows two horses, the rider of one of which leads the other. In the exergue of these coins there are symbols, often of a marine character. All these representations evidently relate to games held in high honour, at which the horse-races were of two kinds,—one the usual contest with single horses, the other that at which every rider had two horses, one of which he rode while leading the other. There must also have been some connection with the sea. Here, as in the case of the chariot-race, the particulars entirely agree with the Olympic games, at which there were the two kinds of horse-races represented—the common one, and that with two horses. As if to remove all doubt, a similar type to those of Tarentum occurs on the coins of Syracuse and Leontini smaller than the tetradrachms. In the case of the former town, a rider is represented on the reverse of didrachms, drachms, and hemidrachms, and in that of the latter, of didrachms and drachms; in each case of the earlier period. In one of the Syracusan examples, Victory flies above the horseman, while in the exergue there is a marine monster; two particulars which complete the parallel with some examples of the chariot-type on coins of the same place. If the explanation of the chariot-type be correct, it cannot be doubted, especially when we recollect the minute agreement in the instance last mentioned, that the similar type which we are considering must be explained in the same manner. It should, moreover, be borne in mind that the two types occur in Philip's coinage, with strong evidence of their meaning, and that it is therefore probable that they have the same signification on the other coins mentioned above; in each case referring to two kinds of contests at the Olympic games. The gold coins of Cyrene, which we have not yet mentioned, have the two types. They present no difficulty. The chariot is always a quadriga, bearing in the earlier examples a figure seeming to represent a common charioteer, but in the later, a Victory driving. The horseman has, in one instance, the traveller's hat, or *causia*, hanging from his neck behind; and here he might possibly be a hero, as on coins of Macedonian kings. As in the case of the Sicilian cities, we find from ancient writers that Cyrene was successful at the Olympic games. It is probable that, at a comparatively late period, perhaps from the early part of the third century B.C., these types lost their proper meaning, and were no longer used with reference to any victory of the city or king issuing the coins bearing them, but were copied in a careless manner from the earlier coinage, or continued with a kind of heraldic intention.

Some objections which are likely to occur to any one considering this question may be here noticed. A similar explanation of the chariot-types was offered by the older writers, and has been abandoned by numismatists, except in the case of Philip's staters. Why, it may be asked, has their explanation fallen to the ground if it be near the truth? We reply, because it was founded on bad criticism, and uncritically developed. It is no matter for surprise that the earlier numismatists should have supposed that these types referred to famous games, for they were always striving to discover some reference to whatever was celebrated in ancient times. Thus far they happened to be right; but the next step led them into error, for, with their accustomed carelessness in such matters, they fixed in any case upon that one of the four sacred games to which the character of a particular device seemed at first sight to point. Such mere guesses, supported by no sound reasoning, were often necessarily erroneous, and the explanation fell into contempt. Nothing but a knowledge of the religious meaning of the types of Greek coins, and of the appropriateness of all their details, could establish a correct explanation. Another objection wears at first sight a more serious aspect. It seems unreasonable that the Olympic games should be commemorated on coins struck in Sicily, in Italy, in Macedonia, and in the Cyrenaica, and not on coins of Greece Proper. We must remember, however, that an Olympic triumph would have been esteemed of far more importance in remote places than those near the scene. The difficulties of the voyage or journey, the long absence of the competitors, and their great expenses, would, in the case of distant cities, forbid any but the most wealthy from engaging in the contest, and raise public expectation to the highest pitch while expecting the event. These conditions would, indeed, scarcely be those of the kings of Macedonia; but they had a special motive for feeling pride in an Olympic success: their country was out of the limits of Hellas, and as none but Greeks could join in the great contest, it was only by proving a Greek ancestry that they obtained, with difficulty, this privilege. The Greeks of Italy, of Sicily, and of Africa, may have felt a similar pride in being able to contend, while their neighbours,

often not only little inferior to them in civilization, but far excelling them in power, were rigorously excluded.

In adopting the explanation given above of two classes of types of Greek coins, we must be careful to avoid an error into which the earlier writers fell. It would be natural to suppose that the coins bearing these types celebrate directly certain victories, or even victors, at the Olympic games, but the principles which regulated the choice of types forbid such a conclusion, while the coins present no direct indications of any relation to individual persons, but in the later period the very contrary. The types were first adopted on occasions at which the city or sovereign acquired distinction at the Olympic games, but not with the intention of a direct historical or personal reference, although there is necessarily such reference of an indirect character. The nature of the difference is well explained by the absence, as far as we know, of any types referring to the foot-race, the successful contender in which was the especial Olympic victor, or to other contests besides the horse-race and chariot-race. In these other contests the victor was personally engaged, whereas in the chariot-race and horse-race this was not necessarily the case, and apparently very unusual; indeed, as to the latter, the evident light weight of the riders represented on the coins proves that, at the period to which they belong, the owners could not have generally ridden their horses. The victors could not, therefore, be directly commemorated by these types. It would be interesting to pursue this inquiry, but we cannot do so in the present article. We would, however, in conclusion, caution students against hastily supposing some apparently similar types to have the meaning of those we have explained. Investigations of this kind must be prosecuted with the utmost care, and coins or types must never be considered singly, except after every effort has been made to gain the illustrative light afforded by similar examples.

The inscriptions of Sicilian coins, particularly the older, are interesting with respect to palæography and for their orthography. We may especially point out the inscription *AKPATANTOZ*, written in the boustrophedon manner on tetradrachms of Agrigentum of the best period. Other instances will be mentioned when we speak of the coinage of the principal towns. We have already noticed the art of Sicilian coins, which may be regarded as on the whole more typical of the western school than that of the coins of Italy. The denominations are, in the case of gold, the same as those of Italy,—Greek in origin, though not wholly identical with any Greek system; in the case of the silver, purely Greek; and in that of the copper, Italian. The silver coins are of very heavy Attic weight, excepting only those of Zancle before it was called Messina, and the earliest of Himera, both which follow the Æginetan system. The principal silver coin is the tetradrachm, which takes the place of the didrachm of Italy. Although the copper money is adjusted to the native Italian system, its art, as with the rest of the coinage, is Greek.

The first coins to be noticed in the series of Sicily are those of Agrigentum. They include gold as well as silver pieces of the period of good art. The most remarkable of the silver are tetradrachms, some of which have on the obverse two eagles devouring a hare, and on the reverse a successful chariot at the Olympic games driven by Victory; while others, as well as didrachms, have on the obverse an eagle standing, and on the reverse a crab. The copper coins are on the Italian system: many of them are of the good period, and of good work. The type most worthy of note is the head of a river-god, with the name *Acragas*, which was that of the river of the town. The success of Agrigentum at the games is attested by Pindar; while Virgil (*Æn.* iii. 704), Gratius (*Cyneg.* 526), and Silius Italicus (*Punica.* xiv. 208-210), mention its ancient renown for horses. Its lofty site (*arduus Acragas*), overlooking the sea, and on the bank of the stream of the same name, makes the eagles, the crab, and the river, appropriate devices, showing that Greek types have a local fitness, while chosen with a religious intention.

The money of Camarina is of especial beauty and interest. The fifth of Pindar's Olympic odes, that to Psamnis the Camarinæan, B.C. 452, affords an excellent commentary upon it. The earliest coin we know is a didrachm of about this time; whereas there are many pieces of from fifty to a hundred years earlier of most of the other important cities of Sicily. Camarina, however, was then but lately inhabited (*νίκας ἰδεν*), having been recently twice devastated by the Syracusans. If there be any older coins, they are probably of a different type. This has on its obverse a helmet upon a round shield, and on its reverse a pair of greaves, between which is a dwarf palm (*Chamaerops humilis*).¹ The arms are perhaps those of Minerva, kept here, as Virgil (*Æn.* i. 16) and Ovid (*Fast.* vi. 46) say the arms of Juno were at Carthage; and the palm might represent the sacred grove (*ἄλυσ ἀγνὴν*) in which the temple of the goddess probably stood. This piece is followed by tetradrachms and didrachms of the best period and of most beautiful work, varying a little in their style. The tetradrachms have on the obverse

Greek
Coins.
Sicily.

the head of Hercules in the lion's skin, and on the reverse Minerva, as a victor at the Olympic games, in a quadriga, a type of which we have already spoken. It was Minerva, protector of the city (*παλαίωχος Παλλάς*), whose sacred grove was made more illustrious by the success of Psauimis. The didrachms have on the obverse the head of a river-god, portrayed as a young man with small horns, and with his hair wet. Of the two rivers of Camarina, the Oanus and the Hipparis, the latter is here represented, for in one case the name is given on the coin. Pindar seems likewise to show the same preference; for while he merely mentions the Oanus (*ποταμὸν . . . Ὀανόν*), he speaks of the sacred channels in which the Hipparis watered the city (*σιμωνὸς ὀχέτους, Ἰππάρκιδος ὄσιν ἄρδαι στρατὸν*). On the reverse the nymph Camarina (*Ὀκισσὸς ἑνὶ γαίῃ . . . Καμαρίνα*) is seen carried across her lake (*Ἰππάρκιδος . . . λίμνην*) by a swan swimming with expanded wings, while she aids it by spreading her veil in the manner of a sail. Some of these didrachms have on either side, around the chief device, fresh-water fishes. The copper coins of Camarina are on the Italian system.

The series of Catania comprises fine archaic tetradrachms and others of the time of the best art, which are handsome, though mannered. The reverse-type of the latter is a victor at the Olympic games in a quadriga, passing one of the metæ, which is a column of the Ionic order. Gela is represented by coins in the three metals. The archaic tetradrachms and didrachms must be especially mentioned. The former have on the obverse the fore-part of the river-god Gelas, whence the city took its name—

“Immanisque Gela fluvii cognomine dicta”

(*Æn.* iii. 702), as Agrigentum did from the Acragas, and Camarina from its lake. The Gelas is represented as a bull, having the face of a bearded man. On the reverse is a victorious biga at the Olympic games, in some examples represented passing a metæ, which is an Ionic column, and resembles that on coins of Catania. A tetradrachm of the later portion of the time of good art, with the types of the fore-part of the Gelas and the victorious chariot, here a quadriga, is remarkable for having above the latter a bird, doubtless an eagle, taking the place of Victory. A tetradrachm of the commencement of the period of good art, and of the highest western style, characterized by a slight severity of treatment, has on the obverse the head of the Gelas, as a young man horned, surrounded by three fresh-water fishes; and on the reverse Victory in a biga, with a wreath above. The accompanying inscription is ΓΕΛΑΔΙΟΝ. Some of the copper coins are beautiful, but not of the finest style. The money of Himera is of great interest. The earliest pieces are didrachms, which, like the series of Zancle, follow the Æginetan talent. No other Sicilian cities are known to have struck coins on this weight. The oldest didrachms of Himera, which probably commenced in the sixth century B.C., bear on the obverse a cock, and on the reverse an incuse type. They are succeeded by archaic tetradrachms, which bear on the one side a victorious chariot, and on the other a nymph sacrificing, near whom a little Pan, or Paniscus, stands beneath the stream of a fountain issuing from a lion's head in a wall. The fountain no doubt represents the hot spring of the place, from which it was afterwards called Thermæ. Leontini is chiefly represented by archaic tetradrachms and didrachms; but there are a few tetradrachms of the early part of the time of good art. The type of the chariot at the Olympic games occurs on these coins, of both periods. The series of Messana is one of particular value. It commences when the town was called Zancle, or, as it is written on the coins, Dancle, with early drachms and smaller pieces of the Æginetan weight, and of very archaic work. On the obverse is a dolphin, and around it a sickle; and on the reverse is a shell in the midst of an incuse pattern. The place is said to have received its name on account of its resemblance in form to a sickle (*ζάγκλον*, or *ζάγκλη*), like the town of Drepanum, or Drepana, in Sicily, and probably the promontory of Drepanum of the Peloponnesus. If there were no religious meaning attached to these names, this early design of Zancle would be an instance of what is termed a speaking type. It is more reasonable, however, to suppose that in each case there was a primary religious meaning in the names, and indeed later writers say that the sickle of Saturn was buried here, and at the Sicilian Drepanum, the descriptive character offering a secondary meaning. Next to these first coins of Zancle may be placed, as the oldest piece of the Attic weight, a tetradrachm with the Samian types,—a lion's scalp on one side, and on the other the head of a bull, and bear-

Greek
Coins.
Sicily.

ing the inscription ΜΕΣΣΕΝΙΟΝ (for *Μεσσηνίων*). This coin was doubtless struck during the rule of the Samians, who took the place about B.C. 494, at the instigation of Anaxilaus, tyrant of Rhegium, by whom they were subsequently expelled. (*Thucyd.* vi. 4.) The next pieces are the earliest of those which have on the obverse a chariot drawn by two mules, and on the reverse a running hare. They most closely resemble coins of Rhegium, with the same devices, and must be assigned, like them, to the rule of Anaxilaus. As we have already mentioned, the period at which this tyrant governed the two towns is thus indicated, particularly as these types cease in the coinage of Rhegium, although they continue at Messana, some of the tetradrachms bearing them being of the period of fine art.¹ The copper coinage is of good work. When the town had been seized by the Mamertini, its name was changed to theirs, which is accordingly borne by the later coins, which are of copper. They are good, but not of the best style. Naxos is represented by handsome archaic tetradrachms and others of the fine period, and by smaller silver pieces, chiefly of the earlier time.

There are some coins of the city of Panormus, but most of those which have been classed to it are of the Carthaginians, issued both in Sicily and Africa. Nothing is more probable than that many of these pieces were struck at Panormus, but there is no means of distinguishing any such, and if there were, the mere fact of their having been issued at the place would not justify us in classing them to it. The Carthaginian coins of Sicily may be best noticed after the Greek coins. Segesta is represented by tetradrachms and didrachms of the archaic and of the good period. One of the tetradrachms of the early part of the latter time has on the obverse the Olympic victorious quadriga, driven by Proserpine, who carries ears of bearded corn, while Victory flies above, about to crown her. The reverse-type represents a hunter, that is, some divinity or mythical hero in that character.

The series of the city of Selinus next demands notice. The first coins are didrachms, bearing on the obverse a leaf, and on the reverse an incuse square, either having several divisions, or else containing a repetition of the leaf. The representation of the leaf is not, either on these or later coins, very exact. The city and its river no doubt derived their name from the plant *σέλινος*, the leaf of which must be here intended. There is some difficulty as to its identification; for in this case, as in those of many other natural objects, the Greeks may have given the same appellation to very different things. The plant sacred at Selinus appears to be, as Colonel Leake supposes, wild celery (*Apium graveolens*);² but it does not follow that that of the same name with which the victors at the Isthmian and Nemean games were crowned was really the same.³ Tetradrachms of a later time, either of archaic style or of that of the earliest part of the period of good art, have devices of more than usual interest. The obverse bears a biga with Apollo and Diana, the latter of whom drives,—a type doubtless referring to the Olympic games; and the reverse exhibits a river-god, the Hypsas, sacrificing at the altar of Æsculapius, while a wading bird is sometimes seen behind him, as if departing. The latter subject appears to allude to the draining of the marshes into the river, by which the place was rendered more healthy. A tetradrachm of the best Sicilian style is important in connection with the opinion we have put forward as to the meaning of the chariot-types. It has on the obverse a quadriga, with two personages, doubtless Apollo and Diana, the former of whom appears to be driving; above them is a wreath, and below an ear of bearded wheat,—the former plainly indicating a victory, the latter connecting the type with a Syracusan one of the same period relating to the Olympic games. The reverse represents the Hypsas sacrificing, as usual.

The illustrious city of Syracuse is worthily represented by its coins. Its early and long-continued greatness in commerce and in arms, its luxury and its love of the arts, are attested as fully by these monuments as by the voice of history. The best do not indeed ever display the breadth and grandeur, and rarely the simplicity, that characterize the highest examples of the medallist art of Greece and her Asiatic colonies, but rather err in an excess of richness and a use of tricks of art; yet the intrinsic beauty of many, and the fine execution of almost all, command great admiration, while the historical value of the series gives it an additional interest. The system of the gold coins of the Syracusans, like that of those of the Greek cities of Italy, is fundamentally on the Attic standard, but presenting some remarkable differences. Thus, although there are gold drachms and hemidrachms, there are also pieces respectively

¹ On the early coins of Messana compare Millingen's paper in *Trans. R. Soc. Lit.*, vol. i., pt. ii., pp. 93, et seq.; and p. 363, *supra*.

² *Numismata Hellenica*, "Sicily," &c.; *Oxford Essays*, 1857, "Sicily," p. 79.

³ Plutarch narrates a story of Timoleon which illustrates this question, relating that when he was marching from Syracuse to encounter the Carthaginians, as his soldiers were going up a hill, on the other side of which they expected to see the enemy, they met mules carrying parsley (*έλάνα*). This they took as a bad omen, because of the Greek custom to crown the sepulchres with parsley, which occasioned the proverb, of one dangerously ill, that he should have parsley. But their leader encouraged them by saying that Fortune had brought them their crowns before victory, because the Corinthians held the crown of parsley sacred, and then decorated with it the victors at the Isthmian games. (Plut. *Timoleon*, cap. xxvi.)

Sicily.

as heavy as one and a half of each of these denominations. The oldest examples are of the early part of the period of good art, and therefore date from about the middle of the fifth century before the Christian era; and the latest probably immediately precede the reign of Agathocles (B.C. 317), the first tyrant whose name we find on the coins. There are some of these pieces which show marks of decline, but the greater number are of good work. One of the finest has on the obverse a head of Apollo, and on the reverse one of Diana, very differently treated,—the former having an ideal character, but the latter resembling a portrait. Other coins present on the obverse heads of the young Hercules and of other divinities, while the most important reverse-type is a victorious biga. The silver coinage of Syracuse, which follows the Attic talent, presents many denominations. The decadrachms, though rare, are more common than those of any other city. The tetradrachms are extremely numerous, and evidently formed, at almost every period until about the time of Agathocles, the bulk of the silver coinage, the smaller denominations being of less frequent occurrence. The earliest coins are tetradrachms and didrachms of very rude work, which may be assigned to the later part of the sixth century B.C. The tetradrachms bear on the obverse a charioteer in a biga, and on the reverse an incuse square of four divisions, having in the centre a female head, probably that of Proserpine. The didrachms have a rider on the obverse, and the same reverse-types as the tetradrachms. A little later we find coins of much better execution, having a female head on the obverse, with dolphins, usually four in number, around it; and on the reverse Victory above the chariot or the horseman. Next in time to these are the famous decadrachms, believed to be the coins known as *damaretia*, struck by Damareta, wife of King Gelon, on receiving a present of a hundred talents of gold, which the Carthaginians gave her when she had negotiated peace for them, after their defeat by her husband at the battle of Himera. As this battle was fought in the year B.C. 480, and Gelon died B.C. 478, the date of these coins is very nearly fixed, and may be considered to be B.C. 479. They afford an example of the highest archaic style, a style not without its excellence and promise. The resemblance to Egyptian art is most remarkable, and far greater than we observe in the money of Greece Proper. The obverse bears a female head, probably that of Proserpine, bound with a wreath; it occupies a circle, indicated by a fine line, without which are four dolphins, as though swimming round. The reverse-type represents a chariot, apparently drawn by three horses, in slow action, and driven by a man. Victory flies above, and below is a lion running. The style of the face of the goddess, with the slightly rounded nose, the eye as if seen in front, and the placid expression, no less than the treatment of the horses, at once recalls to one's mind the colossi and battle-scenes of the temples of Egypt. There are tetradrachms of so exactly the same work as these larger pieces that they must have been issued with them. After this time we perceive a rapid change to a much freer style, but yet one that already shows mannerism. The hair of the goddess, now undoubtedly Proserpine, is either partly covered with a kind of bag, or is variously arranged, sometimes in almost a fantastic manner; and the dolphins around are less regularly placed than before. The period of good art may be considered to begin about B.C. 450, and to terminate with the commencement of the tyranny of Agathocles (B.C. 317). The length of this time is partly due to an accident which happened here towards its close—the introduction, when medallie art was fast declining, of coins with the types and style of those of Corinth, where that art had but little decayed; so that there was a kind of recovery, very unusual in ancient money. At the commencement of the period of the best art, we observe some admirable tetradrachms, which, for the beauty of the face of Proserpine, the treatment of her hair, and the vigour shown in the drawing of the horses, now and always henceforward on the civic coins represented at full speed, are in their class quite unexcelled. The finest of these coins known to us is one in the British Museum. It has on the obverse a most beautiful head of Proserpine surrounded by three dolphins, and on the reverse a victorious quadriga, driven by a bearded charioteer. Victory hovers above, holding in her right hand a wreath, and in her left a label bearing the inscription ETAINETO, supposed to be the name of an artist. The names of artists begin to appear on these coins about this time; and the distinction given to this word is by no means a proof that it is not one. Another, but little later, has on the obverse a head of Proserpine with ears of bearded wheat in her hair, and on the reverse a quadriga driven by a winged male genius, while Victory hovers above crowning him. On the obverse is EYM, the beginning of an artist's name, and on the reverse ETO, the beginning of the name of another artist, showing that different hands were employed to design the two sides. Several coins, still somewhat later than this, have on their reverse Proserpine, with a flaming torch in her hand, driving the

victorious quadriga. One of these has for the obverse-type a helmeted head of Minerva. To the same time belongs a tetradrachm with a very beautiful head of the fountain-nymph Arethusa, whose name is sometimes written above in the form APEΘOZA, as in Lord Northwick's admirable specimen, which has also the name of the artist, KIMON, on the fillet. The head is represented facing, but somewhat turned to the left, with the hair loose and as if wet, though skilfully arranged. The reverse bears Proserpine in a victorious quadriga. The name of Cimon also occurs on more than one of the decadrachms of the fine period, which we might otherwise have supposed to have been struck a little later. There may, however, have been two artists of the same name, or one may have worked at different periods of his life in styles varying as much as these. The later decadrachms are not, however, like the earlier, all of the same time; for there are some of an inferior style, which must be referred to a lower date. All were, however, probably struck during the tyranny of the first Dionysius (B.C. 405–368). Their obverse-type is a head of Proserpine, with the hair variously arranged, sometimes partly contained in a bag of net, sometimes bound with corn leaves, and surrounded by four dolphins. The reverse displays the same goddess in a victorious quadriga at full speed, while Victory above is about to crown her; and the reward, a suit of armour, sometimes with the word AΘAA, is seen below. These coins have been commonly considered the finest in the Greek series; but the best of them are excelled in design and in execution by tetradrachms of the same place, and even these cannot be compared to the productions of the pure Greek school, as we have already endeavoured to show. There are other tetradrachms, besides those already mentioned, of about the time of these decadrachms; and some of a later period and inferior work, which are probably of the reign of Dionysius II., and of the republic established by Dion and overthrown by the tyrant. All these have types very similar to those of the decadrachms. The figure in the quadriga of the latest is, however, Victory. After these it is most reasonable to place those didrachms and smaller coins, which, although of Syracusan fabric, have in the former case wholly, and in the latter partly, Corinthian types. They are of good work; and the didrachms so closely resemble those of Corinth, that their issue can only be explained by the supposition of some extraordinary influence on the part of the parent city. This condition is perfectly fulfilled by what occurred at Syracuse on the final overthrow of the second Dionysius by Timoleon the Corinthian (B.C. 344). The depopulated state of the city accounts for the inferiority of those coins which we suppose to have been struck a little before this event; while a large issue of Corinthian coins at Syracuse would agree with the policy of Timoleon. He replenished the population with a body of Corinthian colonists, and sold the houses to them, depositing the proceeds in the treasury; and in accordance with his endeavours to connect the town as much as possible with Corinth, he would naturally, on issuing a new coinage from the sum thus obtained—said to have been a thousand talents (of silver)—have adopted the Corinthian types. There is a kind of hybrid coinage, half Corinthian and half Syracusan in character, which probably succeeded this, and lasted until the reign of Agathocles. The copper coinage of Syracuse anterior to Agathocles does not commence before the period of good art. It is on the Italian system, often of fine design and work, and well deserves the most careful study.

The regal coins of Syracuse are of far inferior interest to those struck in the name of the people. Some of them are beautiful, but none in the highest style of Sicilian art. The series is important on account of the weight of the silver pieces after the time of Agathocles. For these the Ptolemaic talent seems to have been used, their weights being in accordance with it; while the treatment of the portraits is similar to those of the Greek kings of Egypt. Of Hiero II. there are octodrachms, of Queen Philistis tetradrachms and smaller pieces, and of Hieronymus pentadrachms. It is to be observed that the drachms of Philistis have a low Attic weight. It is possible, from the rarity of these silver coins, that they were struck rather as medals than to form the bulk of the coinage. The money of Agathocles is in gold, silver, and copper; that of Hicetas in gold; and that of Hiero II. and Hieronymus, again, in the three metals. Queen Philistis is only known from the coins and an inscription. She must have been the wife of Hiero II. towards the end of his reign, or of one of his sons. Her coins have fine though mannered designs; that of the obverse being her veiled head, and that of the reverse a victorious chariot. The later Gelon is probably a son of Hiero II., of that name, who may have been admitted to some share of regal power.

The town of Tauromenium, represented by five pieces in the three metals, closes the series of those Greek cities of Sicily, which are of high numismatic interest. We must, however, mention the main characteristics of the true Siculo-Punic coins—that is, those

Coins.
Sicily.

Greek
Coins.
Sicily.

actually struck by the Carthaginians in Sicily. It has been usual to place together a large class of Græco-Punic coins, on account of their general similarity. A careful examination, however, shows that they must be separated into two distinct divisions, representing the coinage of the Carthaginians in Sicily and in Africa, as Mr Burgon pointed out in his catalogue of the Thomas Collection. These classes are mainly to be distinguished by their weight, the Sicilian coins being adjusted to the Attic talent, like those of the Greek cities of the island, while the African follow the Phœnician talent; but there is also a general difference in the types and style, which in the former are far more Greek than in the latter, in which Egyptian, or at least African, characteristics may be perceived. The Siculo-Punic coins are in silver and copper, for there are no gold pieces belonging undoubtedly to this series. Tetradrachms are the most numerous of the silver pieces. The most frequent types are, for the obverse, the head of Proserpine, and for the reverse a horse or horse's head, both, especially the horse, being sometimes accompanied by a date-palm. The horse was probably sacred at Carthage, and thus came to be the favourite symbol of the city. In late times the head appears to have become the prevailing form of the symbol. It may be worth while to remind the reader that both Virgil¹ and Silius Italicus² mention the digging up of a horse's head—the symbol, says the former, of the future nation—at the foundation of Carthage; and that the form of this tale given by Eustathius is still more illustrative of the coins. The last writer relates that the founders having discovered the head of an ox, took it as a bad omen, and left off digging; but commencing again about a cultivated date-palm, like that of the coins (φοίνικα πεφυτευμένον, as distinguished from a wild one), found the head of a horse.³ This version of the story may be the origin of the combination of the horse and date-palm upon the Carthaginian money. We may also notice that there are Siculo-Punic tetradrachms with the head of Proserpine and a victorious quadriga, struck in imitation of coins of Syracuse of the same denomination.

(The principal work upon the Sicilian coinage is that of G. L. Castelli, Prince of Torremuzza, which, although published towards the close of the last century, has not yet been superseded.⁴)

The islands near Sicily struck copper coins which are often singular, and always of some interest. Those of Cossura are Phœnician, with an Egyptian character; those of Gaulos are Greek and Phœnician; and those of Melita, Phœnician, showing both Egyptian and Persian influence. Of Lipara there is heavy copper money on the Italian system, having on the obverse a head of Vulcan, and sometimes on the reverse a figure of the same divinity seated, holding a hammer, and a vase which he seems to have just formed.

The Tauric Chersonese. In the Tauric Chersonese there are interesting coins of the city of Panticapæum, the modern Kertch, in the three metals. Their obverse usually bears the head of a Pan, and their reverse a gryphon, or its head or fore-part. The money of European Sarmatia, of Dacia, and of Upper and Lower Mœsia, is chiefly copper of the Greek imperial class. The few coins of earlier times are generally of a coarseness not far removed from barbarism. In European Sarmatia we may notice the autonomous and imperial pieces of Oeibiopolis, and in Dacia the series bearing the name of the province. The Roman colonia Viminacium, in Upper Mœsia, is represented by numerous coins of a late time. Of Istrus, in Lower Mœsia, there are didrachms and drachms having a strange type on the obverse, representing two beardless heads side by side, the one upright and the other upside down. On the reverse is an eagle devouring a fish. The former type has not been explained: it probably relates to some Greek myth. The style of those coins, it may be noticed, is in general fair, though it sometimes approaches to barbarism. There are abundant Greek imperial coins of Marcianopolis and Nicopolis; while Tomis, the place of Ovid's banishment and death, is not unrepresented in this class.

Thrace. The coins of Thrace are of high interest. The oldest are probably of the sixth century B.C., and there are others of all subsequent times, both while the country was independent and while it was subject to the Romans, until the cessation of Greek coinage. Some of the best period are of the highest artistic merit. So long as they maintain any general distinctive peculiarities of fabric and design—that is, from their commencement until the age of Philip—the Thracian coins resemble those of Macedon. They also follow the same talent, that of Macedon, commonly called the Alexandrian

or Ptolemaic. The heaviest tetradrachms are the earlier, which weigh about 232 grains: those issued at later times are generally much lighter. The money of Abdera comprises tetradrachms and smaller coins of the period of archaic and fine art. The principal type is a seated gryphon. Ænus is remarkable for the great beauty of some of its coins. These are tetradrachms of the earliest part of the time of the best art. They bear on the obverse a head of Mercury, facing, in his cap, and on the reverse a goat. The broad, free treatment of the head cannot be sufficiently praised; and it is worthy of remark, that it is here far more effective than the later and artificial style. There are drachms of a period subsequent to that of these coins, which enable us to make this comparison. The money of the ancient city of Byzantium commences with early tetradrachms and smaller coins, having on the obverse a bull above a dolphin, and on the reverse an incuse square of four divisions. Tetradrachms of the late part of the time of good art, bearing the head of Ceres veiled, and with corn in her hair, on the obverse, and Neptune seated, on the reverse, should also be noticed, as well as the long series of copper coins issued under the empire. Of Cosa there are Græco-Roman aurei, which were probably struck by Brutus during the short time that he maintained himself against the triumvirs. They bear on the obverse an eagle holding a wreath in one claw, and on the reverse a figure in a toga between two lictors, with the Greek inscription ΚΟΣΩΝ. There is sometimes in the field of the reverse a monogram of the letters L B, which is supposed to indicate the name of Lucius Brutus, whom we know to have struck Roman money with the more famous Marcus Brutus. The Roman colonia of Deultum is represented by many coins; and the city of Hadrianopolis by a long series, comprising fine pieces. Of Maronea, anciently famous for its wine, there is an interesting series of coins, beginning with very early drachms. After these we notice tetradrachms of the fine period, having on the obverse a horse, and on the reverse a vineyard, conventionally represented by a vine in a square. There are also large tetradrachms of a late time, with, on the one side, the head of an androgynous Bacchus, and on the other the standing figure of a young Bacchus. The Greek imperial coins of Pantalia and Perinthus are worthy of notice. Among those of the latter town we may mention very fine pieces of Antoninus Pius and Severus, and large coins, commonly called medallions, of Caracalla. In the Thracian Chersonese the most important series is one of autonomous silver coins, probably of the town of Cherronesus. The money of the island of Thasos is of much interest. It commences with extremely old silver coins, which appear to be on the Æginetan system. These are followed by a series on the Attic weight, ranging from a very early time to the commencement of the period of good art, some of the latest being of fine style. The obverse-type represents a satyr carrying a female, and the reverse-type is an incuse square, divided, more or less rudely, into four parts. After this we observe coins bearing for their obverse-type the head of Bacchus. Some of these are of the best period of art, and one, a tetradrachm, is among the very finest Greek coins. The head of Bacchus is treated in a sculptural style that is remarkably broad and grand. The massive, powerful features, and the formal hair nearly falling to the neck in regular curls, like those of the full beard, are relieved by a broad wreath of ivy leaves designed with great delicacy and simplicity. The reverse bears a Hercules kneeling on one knee and discharging his bow, a subject powerfully treated. Of a far later period there are large tetradrachms much resembling those of Maronea. They were probably struck, in both places, in the early days of the Roman rule. The money of Lysimachus is of far higher importance than that of any other king of Thrace. The most common pieces are, in gold, staters, and in silver, tetradrachms. The earlier coinage follows the types of that of Alexander the Great. The later coinage, of which the examples are far more numerous, bears as the obverse-type what is considered to be the first Greek regal portrait, the head of Alexander with goat's horns, deified as a young Jupiter Ammon;⁵ the reverse-type is a seated Minerva holding a little Victory. There are coins of the kings of Pæonia, which are chiefly silver, and have a resemblance to those of the Macedonian sovereigns, although they are somewhat barbarous.

The coinage of Macedonia, both civic and regal, is of great variety and interest. It commences at an early time, probably towards the end of the sixth century B.C. The oldest pieces are of silver, copper, and not long afterwards gold, having come into use

⁵ Some have doubted this type to represent Alexander, but the evidence in favour of its doing so must be considered to be conclusive.

Greek
Coins.
Macedon.

for coinage during the fourth century B.C. The types are of a Greek character, with, in the earliest class, a tendency to barbarism. Their art, although at first slow in its development, attained great excellence. The standard of the earlier coins is that of the old Macedonian talent, which is better known as the Alexandrian or Ptolemaic, from its restoration to use in the coinage of Egypt by the first Ptolemy. The weight of its drachm was at first about 58 grains. The heaviest denomination in Macedonia was an octodrachm. The coins of this denomination are of an early period, all dating about the time of Alexander I., and indicate the metallic wealth of the country rather than the success of its trade at that time, since they are more likely to have been coined from the produce of the mines than from silver acquired in commerce. Philip II. adopted for gold money, which he was the first Macedonian king to issue, the Attic weight, striking staters on that system, while he maintained the old standard for his silver coinage. Alexander the Great made the weight of the gold and silver money the same by using the Attic system for both; and from his time no coins of kings of Macedon, in these metals, were struck on any other.

The series of Macedon commences with coins of the kingdom or province bearing the name of the Macedonians. Some of these seem to have been issued under the kings, but others are of the Roman domination. The money of Acanthus comprises fine archaic tetradrachms, and others of the commencement of the period of good art. The type of their obverse is a lion seizing a bull. There are smaller pieces of various kindred types. The money of Æneia is chiefly interesting from its bearing the head of the hero Æneas. The town of Amphipolis is represented by a long series. There are tetradrachms having on the obverse a head of Apollo facing, which are of fine work, but not in the severe and best style. The reverse-type is a torch in an incuse square. Other silver, as well as copper coins, display good art. There are also many Greek imperial copper pieces of this place. The territory of Chalcidice is pre-eminent for the high excellence of some of its silver coins. These are tetradrachms of the best period, and of an admirable style. The more important design is that of the obverse, representing a head of Apollo in profile, crowned with laurel. It is in very high relief, and treated with great simplicity, though not with the severity of somewhat earlier pieces. The delicacy of the features is balanced by the shortness of the hair, and the broad, heavy wreath of laurel. On the reverse is a lyre of seven strings. Other tetradrachms are of comparatively coarse work. There is an early series of coins of Iete. Some are of a remote date, and none later than about the time of Alexander I. The obverse-type is a Pan or faun with a nymph, and on the reverse is an incuse square. These coins are nearly all tetradrachms. Of Neapolis there are archaic silver and copper coins, with, on the one side, a Gorgon-head, and on the other a head of a female. The coins of Philippi are in the three metals. The gold pieces are fine staters, with the head of Hercules in the lion's skin on the obverse, and on the reverse a tripod. The silver and early copper pieces have the same types. The style of all points to the reign of Philip II., who, having discovered or gained possession of a rich gold mine near Crenides, changed its name to Philippi. Pydna is represented by copper money of the best period, sometimes fine, and, in the case of one specimen we have seen, very beautiful. There is a long series of Greek imperial coins of Thessalonica. Trilium must also be mentioned on account of its archaic silver coinage, and for the excellence of some of its copper money of the best time. The class of uncertain coins of Macedonia is deserving of careful study. It comprises very early silver pieces, among which octodrachms of the Macedonian talent should be especially noticed. One of the latter, and a smaller piece, bear inscriptions which have caused them to be attributed to the Orestæ, but both Millingen and Colonel Leake assign them to a people of Thrace, not otherwise known to us, whom they call the Orescii, from the inscriptions of the coins. There are also two coins of Geta, King of the Edoni, a prince of whom we have no other record. They are octodrachms of about the period of Alexander I. On the obverse is represented a hero wearing a causia driving two bulls, and the reverse bears an incuse square of four divisions, having around it on one coin ΓΕΤ[Α]Σ ΒΑΣΙΛΕΥΣ ΗΑΟΝΑΝ, and on the other ΓΕΤΑΣ ΗΑΟΝΕΟΝ ΒΑΣΙΛΕΥΣ. The difference, not alone in construction, but in orthography, and the use of long and short vowels, is very remarkable, and seems to indicate barbarism, since the coins are unquestionably of the same period. Both were found in Babylonia by Mr Rich,—a circumstance that finds its explanation either in the commercial importance of the Macedonian silver at this time, or in the probability that the remains of the armies of Darius and Xerxes carried away with them some Greek money taken as plunder.

Greek
Coins.
Macedon.

The coinage of the Macedonian kings, since it includes the money of Philip II. and that of Alexander the Great, is equal in interest to any other Greek regal series. The oldest pieces are of Alexander I., the contemporary of Xerxes. These are octodrachms, resembling those of Geta, King of the Edoni, but having on the obverse a hero by the side of a horse; and coins of a lower denomination with the same type. The next king known by his coinage is Archelaus (B.C. 413-399), of whose reign we have silver coins, some of which are of archaic, and others of fine work, as well as the earliest copper money of the series. Of Amyntas II. (B.C. 397-371) there are coins of fine work, both in silver and copper. The money of subsequent reigns is not remarkable until that of Philip II. His gold pieces are staters and a small division. The abundance of the former is attributable to his having possessed the gold mine of Philippi. The staters are Attic didrachms, and are of fine, but not of the highest art. They bear on the obverse the head of young Hercules,—not of a sufficiently manly cast, and resembling that of Apollo, though rightly attributed to the former divinity by Mr Burgon. On the reverse is a goddess in a victorious Olympic biga, a type we have already explained: in one case Victory flies before the horses. These coins were afterwards known as *φιλιστικα*, and the gold money of Alexander as *Αλεξανδρινα*—appellations which probably did not include larger or smaller pieces. Horace calls the gold coins of Philip, "Philips" ("regale nomisma, Philippos"). (*Epist.* ii. l., v. 232.) The silver coinage of Philip is exclusively composed of tetradrachms of the Macedonian talent. Their type of obverse is a head of Jupiter; and of reverse either a mounted hero wearing a causia, or a victor in the horse-race with a palm, a design already discussed. There is a difficulty in deciding as to the copper money of Philip.

The coinage of Alexander the Great, both in the number of the cities where it was issued, and in its abundance, excels all other Greek regal money; but its art is, without being despicable, far below excellence. The types are not remarkable in themselves, and there is a great sameness characterizing the entire series. The system of both gold and silver is Attic, Alexander having made the money of these metals uniform in weight by substituting the Attic for the Macedonian silver talent. The gold coins are distaters or gold tetradrachms, hemistaters or drachms, with their half, and a smaller denomination. The types of the distaters and staters—the latter of which were the most common pieces—are, for the obverse the head of Minerva, and for the reverse Victory bearing a standard. The largest silver piece is the decadrachm, of which there is but a single specimen known, now in the British Museum. The types of the tetradrachms and most of the lower coins are, on the obverse the head of young Hercules in the lion's skin, and on the reverse Jupiter seated, bearing on his hand an eagle. The head has been supposed to be that of Alexander; but this is not the case, although there is probably some assimilation to his portrait. The great currency was of tetradrachms, which were struck in different cities, distinguished by proper symbols and monograms. The classification of these coins is difficult, and has not been sufficiently studied. The copper money is not remarkable. (There is an essay upon Alexander's coinage by M. Müller of Copenhagen, which will be found of service in its examination.)

The coinage of Alexander is followed by that of Philip Arrhidæus, in gold and silver. To Alexander Ægus no money has been assigned with certainty; but it is probable that coins in silver and copper, usually attributed to Alexander II. of Epirus, were issued by Ptolemy I. in Egypt in the name of this titular sovereign. The obverse-type of these is a head of Alexander the Great, like that on the coins of Lysimachus, in the silver pieces covered with the skin of an elephant, and in the copper ones bare. The money of Cassander and his sons Philip IV. and Alexander IV. is not remarkable. The coins of Antigonus, King of Asia, are placed in the Macedonian regal series, since he was a successor of Alexander, and his son Demetrius gained the Macedonian sovereignty; but this is scarcely a correct classification. He struck very fine tetradrachms, having on the obverse a head of Neptune, and on the reverse Apollo seated on the prow of a galley,—types indicating the naval power of this king. The coins of Demetrius I., Poliorcetes, comprise fine tetradrachms, the types of which have a similar reference. They bear either, on the obverse his portrait horned, and on the reverse a figure of Neptune, or on the one side a winged female figure (Victory)² in the prow of a galley, blowing a trumpet, and on the other Neptune striking with his trident. The latter types cannot be doubted to relate to the great naval victory which Demetrius gained over Ptolemy. The tetradrachms of Antigonus I., Gonatas, which are of inferior style and work to those of Demetrius, have types which appear to refer in like manner to the great event of his time. Their obverse-

² Eckhel supposes this figure to be Fame, but in this instance he seems to have judged hastily (*Doct. Num. Vet.*, vol. ii., pp. 120, 121).

Greek
Coins.

type is a Macedonian buckler, with the head of Pan in the midst; and their reverse-type Pallas Promachus. The head of Pan is supposed to have been taken as a device in consequence of the panic which led to the discomfiture of the Gauls at Delphi,—panics being attributed, as the name imports, to the influence of Pan. The money of Demetrius II. and Antigonus II. is unimportant. The tetradrachms of Philip V. have, on the obverse two kindred types, in each case a head in the helmet of Perseus, but one apparently representing Philip in the character of that hero, and the other the hero himself, though probably assimilated to the king. The reverse bears a club. Other tetradrachms and smaller coins have a simple portrait of Philip. The tetradrachms of Perseus are of a fair style, considering the time at which they were struck. They bear on the one side the king's head, and on the other an eagle on a thunderbolt.

Thessaly.

The coinage of Thessaly presents very few specimens of a remote period, while coins of the best time are numerous. The latter are in general remarkably like the finest coins of Sicily and Italy, although there are some of a severer style. The weight is generally, if not always, adjusted to the Æginetan talent. Of the town of Gomphi or Philippopolis there is a beautiful drachm, having on the obverse a female head facing, which is probably that of Juno. The coins of Larissa are also to be noticed for their beauty. The series of Larissa is well worthy of a careful examination. It commences with archaic pieces, and some of the early period of good art, but of rather coarse execution. These are followed by coins of fine work. The usual obverse-type is the head of the nymph of the fountain facing, and on the reverse is generally a horse, either free or drinking. On some the head is treated in a very rich manner, like that of the fountain-nymph Arethusa, facing, on tetradrachms of Syracuse; indeed, in one case, the resemblance, in its obverse, of a didrachm of this place to these Sicilian coins is most remarkable. The small silver pieces have very interesting types, relating to the nymph of the fountain, and to be compared for mutual illustration with the common didrachms of Terina and with some of those of Elis. The copper money is also fine. The coins of Pharsalus and Pheræ are worthy of note. Of the tyrants of the latter town, Alexander and Tisiphon are represented by their coins; but we agree with Mr Burgon in thinking the tetradrachms which have been ascribed to the former to be of a king of Pæonia. The coins of Tricca resemble those of Larissa.

Illyricum.

The coinage of Illyricum is poor and rude. The weight is at first Æginetan, but afterwards it appears to have been generally Attic, a change probably attributable to Corinthian commercial influence. Of Apollonia there is a large series of Attic drachms, the most important type of which is a reverse one representing three nymphs dancing around what appears to be a burning hillock, but may be intended for a volcano. There are also a few Greek imperial pieces. Dyrrhachium, which never, as far as is known, bears on its coins the more famous name of Epidamnus, is represented by an important series. First, there are Æginetan didrachms, with Cocyraean types,—on the obverse a cow suckling a calf, and on the reverse a device supposed to be a kind of ground-plan of the famous gardens of Alcinoüs. These are succeeded by didrachms with Corinthian types, and, of course, on the Attic standard; and then the old types are resumed, but apparently without a return to the former weight. Dyrrhachium, it should be remembered, was founded partly by Cocyraean and partly by Corinthian colonists. The Corinthian types are, however, to be at least mainly ascribed to subsequent influence, although their adoption may have been furthered by the recollection of the origin of the town. A didrachm of the first class bears the name of a King Monunius, who has been supposed to be the Illyrian prince Monunius mentioned by Livy and Athenæus, and who reigned about B.C. 180. All the Æginetan didrachms, however, must be concluded to have been struck from about B.C. 400 to 300, the Attic money supplanting them at near the latter date; and therefore this supposition is not tenable.

Epirus.

The coins of Epirus are of higher interest and beauty than those of Illyricum. The weight is generally Æginetan, except in the regal series, which follows the Attic standard. Of the Epirotes there are silver coins which appear to be Æginetan didrachms and drachms of low weight. They are of about the time of Pyrrhus and of a later period. The city of Ambracia is represented by beautiful silver pieces, with, on the one side a veiled female head, and on the other a kind of obelisk. Of Damastium there are rude coins, which are doubtless of an early period. The long series of Greek imperial money of Nicopolis must also be mentioned.

The coinage known to us of the kings of Epirus begins under Alexander I. His coins have been found in the three metals, but they are rare. It is probable that they were struck in Italy while he was in that country. The coins of Pyrrhus are of high interest, and remarkable for their beauty, although in a greatly decorated style. There can be little doubt that they were for the most part struck in Italy and Sicily—at Tarentum, Syracuse, and probably other towns also. Some of the gold pieces are fine, but the silver are more worthy of note. The tetradrachm has for the type of the obverse a head of the Dodonæan Jupiter crowned with oak, and for that of the reverse Juno seated. A fine didrachm bears on the obverse a young male head helmeted, which we believe to represent Pyrrhus, though in a peculiar manner. It is said that Pyrrhus was judged by his contemporaries to bear a great resemblance to Alexander in face and manner;¹ and if we compare this head with that king's on the coins of Lysimachus, we perceive a remarkable similarity. There is what we should call a strong family likeness, if the term be admissible, between the two. The features are not alone similar, but they have the same animated expression. Visconti considered the head in question to be that of Pyrrhus, and brought forward the argument given above, but he did not meet the objection that the treatment is ideal. This difficulty is overcome if we consider it to have been an idealized portrait of Alexander assimilated to that of Pyrrhus, as the head of Hercules on the money of the former king is probably assimilated to his own. The portrait of Alexander on the coins of Lysimachus, and again on those which we suppose to be of Alexander Ægus, is also ideally treated, more especially in the latter case.² Among the copper coins of Pyrrhus we must remark the beautiful ones with the portrait of his mother Phthia. The money ascribed to later kings of Epirus is of doubtful attribution.

The coinage of the island of Corcyra generally, or of the Corcy-Corcyra, commences with very early didrachms and drachms of the Æginetan weight. These are followed by coins of the early part of the period of good art, but usually somewhat rudely executed. The types of the didrachms of this and the preceding group are, on the obverse a cow suckling a calf, and on the reverse the supposed gardens of Alcinoüs, both, as we have seen, like those of the first didrachms of Dyrrhachium. These are followed by coins with, on the one side, the head of an androgynous Bacchus, and on the other a Pegasus. The former of these types is illustrated by the fame of the wine of Corcyra in ancient times; the latter by the colonization of the island from Corinth, to which town this type must be held to refer. These and the later coins are probably on the Attic standard. Copper money is abundant, both of the autonomous and the imperial class. There are, however, no pieces which can be considered to be of very fine art in either silver or copper.

The coins of Acarnania are not remarkable for beauty, or for Acarnania variety in their types. We must mention those of the Acarnanians, which are Æginetan didrachms and drachms, having on the obverse the head of the Acheloiüs, beardless, and covered with a bull's skin, and on the reverse a seated Apollo. These are probably of about the time of Alexander the Great. Of Leucas there are silver and copper coins, the latter being numerous; and of Ceniadæ, copper, with, on the one side the head of Jupiter, and on the other that of the Acheloiüs, bearded, and in a bull's skin. The honour in which the Acheloiüs was held explains the occurrence of its head in more than one series.

In Ætolia, the money of the Ætolians must be mentioned. The Ætolia gold and silver coins are fine, but not of the best period or of a very good style, and are probably to be referred to about Alexander's time. The gold pieces have on the obverse the head of Minerva or that of Hercules in the lion's skin, and on the reverse Ætolia, personified as a female seated on shields, with a little Victory on one hand. There are similar types on the silver coins; and the drachms bear others relating to the chase of the Calydonian boar. The latter have on the one side the head of Atalanta wearing a causia, and on the other the boar and the spear-head with which he was killed. The standard is first Æginetan, and then Attic.

In Locris the coins of the Locri Opuntii, no doubt struck at Opus, Locria claim our notice. There are didrachms and hemidrachms on the Æginetan weight, of the best period, and of a style which is admirable, notwithstanding that it is very rich in the treatment of the subject occupying their obverse. This is a head of Proserpine, with corn-leaves in her hair. The reverse bears a warrior in a fighting attitude, with sword and shield. His name, ΑΙΑΣ, which is sometimes written beneath, shows that he is the Lesser Ajax, who led the Locrians to the siege of Troy.

Greek
Coins.

Epirus.

¹ Καὶ γὰρ ὅψιν φοντα καὶ τάχος ἰσχύει καὶ κίνημα τοῖς Ἀλεξάνδρῳ καὶ τῆς φωνῆς ἰσχύει καὶ βίαια παρὰ τοὺς ἀγῶνας ἐν τούτῳ σκιάς τινος ὁρᾶσθαι καὶ μιμήματα, τῶν μὲν ἄλλων βασιλίων ἐν πορφύρεσι καὶ δορυφόροις καὶ κλίσι τραχήλου καὶ τῇ μετῴν διαλέγεσθαι, μόνον δὲ Πύρρῳ τοῖς ἔσλασι καὶ ταῖς χρίσιν ἐκδιαικνύμενον τὸν Ἀλεξάνδρῳ. (Plut. Pyrr., cap. viii.)

² Millingen (Considerations, Supp., pp. 27, 28) supposed the head on the didrachm of Pyrrhus to be intended for that of Achilles, and his opinion has some support from the occurrence of the letter A in the field. This letter would, however, be equally appropriate in the case of Alexander.

Greek
Coins.

There are silver coins of the Phocians and of Delphi. Those of the former are of archaic and of fine art, and follow the Æginetan system. The coins of Delphi, which are on the same standard, are not an important series. Among them are Greek imperial pieces, some of which have a representation of the famous temple on the reverse.

Bœotia.

The coinage of Bœotia forms an interesting series. It is chiefly of a period anterior to the reign of Alexander, under whom the political importance of Thebes and the whole country came to an end. The silver money is fine in its art, and a great similarity is observable in its fabric and types. The standard is Æginetan, but the Attic must have been introduced after Alexander's time, as there are some specimens of its weight. The copper money is poor. Of the Bœotians there is a long series. The great currency was of Æginetan didrachms, but many smaller coins are found. In the archaic pieces the obverse-type is a Bœotian buckler, which is probably that of Hercules, and the reverse bears an incuse square. On coins of the early part of the time of good art we find the buckler and a diota; the former seeming to stand for Hercules, and the latter for Bacchus, corresponding to the types of Thebes with the head of Bacchus on one side and Hercules on the other. Later coins of these types, and of a very fine style, bear on the reverse the earlier letters of proper names, which can only be of magistrates. One, a didrachm, may be particularized for its beauty and on account of the inscription ΕΠΙΑΜΙ, which Mr Burgon supposes to be part of the name of the illustrious Epaminondas, an opinion which the style of the coin corroborates. On this piece there is a rose above the diota. The other names require to be carefully studied. There are still later pieces of inferior work. Very rare tetradrachms of Attic weight, standing quite by themselves in the coinage of Bœotia, must be referred to a time subsequent to that of the silver coins of Æginetan weight. Their obverse-type is a head of Jupiter, and their reverse-type a seated Neptune.

The coinage of Orchomenus is fine. Very beautiful hemidrachms of the best time, with the head of Proserpine on the obverse, must be particularized. Of Tanagra there are coins of the archaic and the good period. The money of these lesser towns cannot, however, be compared for importance to that of Thebes. A few small gold coins have been found of this city; but the great currency was of silver, and chiefly in didrachms, of course on the Æginetan standard. The earliest silver pieces must be assigned to a time not long after the beginning of Greek coinage. These have on the obverse the usual buckler, and on the reverse an archaic Θ in the midst of an incuse pattern. After these there are pieces of early good style and others of rich work of a later time, although also of the age of the best art. The types appear mainly to relate to Hercules and Bacchus. We may notice didrachms, with on the obverse the buckler, and on the reverse the diota, with the buckler, and the infant Hercules strangling serpents, and with the head of Bacchus, and Hercules stringing his bow. The last reverse-type is a very fine example of the early work of the good time. The copper money is not remarkable. The only other Bœotian town which need be mentioned is Thespiæ, of which there are silver coins of a late archaic time.

Attica.

In Attica the great series of Athens demands our consideration. The gold money is not common, and of a late time, probably near that of Philip. The pieces are staters or didrachms. The silver is very plentiful, and must anciently have had a high commercial importance. We have already spoken of the denominations in treating of those of Greek coins generally. It may be here mentioned that the decadrachm of Athens is extremely rare; that the most common coin is the tetradrachm; and that some of the smaller pieces are of frequent occurrence. The earlier coins have archaic types, commencing about B.C. 500, and reaching down, without any essential change of style, through the period of good art,—a circumstance which can only be attributed, as already remarked, to a desire not to injure the credit of the Athenian money for purity among the nations which received it in trade. They are thick and of coarse fabric. There was no doubt a still older Athenian coinage, of which specimens must remain; but on this subject nothing satisfactory has as yet been published. The most notable coins of the earlier class are the decadrachm, which has on the obverse the head of Minerva, and on the reverse an owl with spread wings, with the inscription ΑΘΕ, and an olive branch, and the tetradrachm, with the same obverse, and on the reverse an owl, usually turned to the right, but sometimes to the left, and more rarely facing, but with its wings closed. The coins of the later class are thinner, and consequently broader, and of a more recent style, than those of the earlier. They probably commenced not long after the time of Alexander, and lasted until that of Sylla, if not later. The principal pieces are tetradrachms, each bearing the names of three

Greek
Coins.

magistrates, among which occur those of two kings, Antiochus (doubtless the third of that name), and the famous Mithradates of Pontus. Their obverse-type is a head of Minerva, probably copied from that of the ivory-and-gold statue by Phidias in the Parthenon, rather than that of the bronze one by the same artist on the Acropolis; and their reverse-type is an owl upon an amphora. The Athenian copper is of low art. The first attempt to introduce it failed;¹ but the principal piece (χαλκοίς) was common in the time of the poet Philémon,² about B.C. 300. The most remarkable copper coins are two bearing representations of the Acropolis and the great edifices. Both have on the obverse a head of Minerva. The reverse of one represents the Acropolis, with the grotto of Pan, the statue of Pallas Promachus, the Parthenon, and the Propylæa, with the steps leading up to the latter. The reverse of the other shows the theatre of Bacchus, above which are caverns in the rock, and higher still the Parthenon and the Propylæa.³ Respecting the rest of Attica we need only remark that there are fine copper coins of Eleusis, and that there are Greek imperial pieces of Megara.

The money of the island of Ægina is of especial interest, since Ægina. with it Greek coinage is said to have originated. The story is, that at a time when Ægina was a dependency of Argos, Phidon, king of Argos, struck the first Greek money there, in the eighth century B.C. It is said that previously silver was formed into spikes (σβελισκoi), of which six made a handful (δραχμη); and that thus the name of the drachm and its sixth, the obolus, originated; but this account may be an invention of later times. There can be no doubt, however, that the earliest Æginetan coins are of extreme antiquity. The weight is of course on the talent of Ægina. The oldest pieces are very primitive didrachms, bearing on the obverse a tortoise, and on the reverse a rude incuse stamp. Afterwards the stamp becomes less rude, and later has a peculiar shape. There are some coins of the early part of the fine period, and of excellent work. The great currency was of didrachms. The copper coins are not remarkable, but some appear to be of a time anterior to most Greek pieces in this metal.

The series of Achaia is numerous and interesting. First we Achaia. must mention the coins of the Achæan League. The principal pieces appear to be tetrobols, since their weight is about that of two-thirds of a light Attic drachm. The type of the obverse is a head of Jupiter, and that of the reverse ΑΧ, for ΑΧΑΙΩΝ, in a monogram, with the name of the people by which the coin was issued, either in full, or represented by its commencement, commonly the latter, and generally some distinctive symbol. There is also copper money of this confederacy. Corinth is represented by a very large series of coins, the weight of which is always Attic. The chief coin was the didrachm. The oldest pieces are of a very early time, and bear on the obverse a Pegasus, and on the reverse an incuse pattern. On coins of a subsequent time, of archaic style, latterly approaching to that of the good period, we find the Pegasus still on the obverse, but on the reverse the head of Minerva in an incuse square. Of the period of the excellence and decline of art there are numerous specimens, some of which are of beautiful work, although generally devoid of the severity of the highest Greek art. The didrachms have on the one side a Pegasus, either galloping, which is most common, or standing, or drinking; and on the other the head of Minerva, sometimes with a laurel-wreath on the helmet, which, it may be noticed, is always Corinthian. The old letter koppa, the initial of Corinth according to the archaic orthography, is generally seen on the obverse, as well as various symbols and letters, on the reverse. The smaller coins have the same obverse, but generally on the reverse a head of Venus, sometimes in a cap. Some of these, which appear to be principally tetrobols, are of good work; and there are a few of fine early style. There are some drachms with Bellerophon in a combatant attitude, mounted on Pegasus, on the one side, and the Chimæra on the other. The autonomous copper money is poor, but often of fair work, and interesting, especially when the type relates to the myth of Bellerophon. Under the Romans this city was made a colonia; and we have a large and interesting series of the copper coins struck by it as such. To the colonies of Corinth is assigned a large series of silver coins, chiefly, at least, didrachms,—for it is doubtful if there are smaller pieces,—with the common types of the parent city. These coins probably do not, in some cases, indicate anything more than Corinthian origin,—and there can be no doubt that the didrachms of Corinth had such a reputation in commerce that other cities would have been ready, when it was possible, to issue similar pieces,—but in other cases they are witnesses of a contemporary influence or actual supremacy of that great mart.

There are copper pieces of Patræ as a Roman colonia, and silver and copper coins of Phlius, both of the period of good art. The ancient city of Sicyon is remarkable for the great beauty of its

³ See *Numismata Hellenica*, "European Greece," 21, *et seq.*

Greek
Coins.

money. Notwithstanding its reputation for antiquity, no coins of the archaic time have been attributed to it. The silver coins commence in the time of early good art, and continue until a late period, perhaps not far from that of the Achæan League. The standard, at least during the good time, is Æginetan. The most beautiful specimen known to us is a drachm of an excellent and simple style, having on the obverse a dove, as if alighting, and on the reverse the letter Σ , placed horizontally like M, with an ornament beneath it. There are didrachms of a somewhat later time, which, although very fine, are a little too decorated, or at least not severe, in their style. The type of their obverse is the Chimæra, and that of their reverse a flying dove within a wreath. The copper is mainly of good time, but some pieces may be late.

Elis.

The money of Elis, or the Eleans, forms a most interesting series, many of the silver coins being of the highest style, and almost all bearing interesting devices, remarkably executed. The weight is Æginetan; and didrachms must have been the most important coins. The inscription, in full $\Phi\Lambda\Delta\epsilon\iota\omicron\omicron\omicron$, is remarkable for the use of the digamma. The earliest coins are thick pieces of archaic work, and singular style, probably struck about the time of the expedition of Xerxes. The obverse bears a flying eagle carrying a serpent, and the reverse, a thunderbolt, sometimes of an elaborate form. Later archaic coins have the eagle carrying a hare or serpent, and a winged female figure. Next in order of time are the first fine coins. Some of these have on the obverse an eagle preying on a hare, and on the reverse a winged female figure seated on a base. This reverse is very beautiful in one example we have examined. Still later than these are coins of the finest style. On the obverse is a head of Juno, in a tiara, with honey-suckle ornaments, and sometimes bearing her name HPA ; and on the reverse an eagle, or a thunderbolt, within a wreath. The head of Juno is an admirable design, and fully proves that the Greeks attained as great success in coin-engraving as in sculpture. Not only is the face most beautiful, but it is perfectly appropriate to the character of Juno as drawn by the poets, and fit for the form and surface of a coin. There are also pieces in a later style. The copper money is not remarkable.

Cephal-
lenia, &c.

We have next to notice the coinage of the island of Cephallenia. The very early and archaic silver coins of Crani must not be passed by, nor the money of Pale and Same, all cities of this island. Of the island of Zacynthus there are silver coins, usually of rather coarse work. Didrachms of the early good style, on the Æginetan standard, must be mentioned. The coins of Ithaca are of copper. They are of interest on account of their common obverse-type, which is a head of Ulysses.

Messenia.

Returning to the mainland, we first notice the money of Messenia, or the Messenians. The most remarkable coin is an Æginetan didrachm of the finest style, having on the obverse a head of Proserpine, excelling in design the similar subjects on the money of Syracuse. On the reverse is a figure of Jupiter. The other silver coins are of a comparatively late time, many being of about the period of the Achæan League. The copper money is plentiful, but not interesting. In Laconia it is only necessary to mention the coinage of Lacedæmon. As we might have expected, there are no early coins, the silver money being, like so much of that of the Greek cities, of about the time of the Achæan League. Among the types of the autonomous copper pieces may be noticed the head of the Spartan lawgiver, with the inscription ATKOTPOC .

Argolis.

The series of Argos in Argolis commences, as one would have anticipated, with coins of a very early period. The standard is Æginetan. The first coins are the drachm, with a wolf on the obverse, and on the reverse A, the initial letter of the name of the people and city, in an incuse square of two divisions, and the hemidrachm and a smaller piece, each with a wolf's head on the obverse, and the same type of reverse as the drachm. The most common silver coins have as their obverse-type the fore-part of a wolf; and the head also occurs on smaller pieces. Among coins of the period of good art we must especially notice those which have for the obverse-type the head of Juno wearing a tiara; a design which, although sometimes of great beauty, is not equal to that of the coins of Elis, the style being less simple. A reverse-type of one of these coins, a drachm, represents Dioned stealthily advancing with the Palladium in his left hand, and a short sword in his right. On coins of the period to which this belongs (for it is certainly anterior to Alexander), the devices were of a strictly religious character. We cannot suppose a historical subject to be introduced; and it is therefore evident that the Trojan war was then considered by the Argives to be mythical. It may be remarked that some of the copper coins of Argos are of good style. Of the town of Trœzen

there are very fine silver coins of the early part of the best period of art, and some of a later time.

Greek
Coins.

The money of Arcadia is interesting, although it does not form a large series. Some pieces are doubtless among the most ancient struck by the Greeks, and the types of these and later coins are often connected with the remarkable myths of this primordial part of Hellas, showing particularly the remains of its old nature-worship.

Arcadia.

The first series to be noticed is that of Arcadia generally, or the Arcadians. It commences with very ancient silver coins, probably of at least the sixth century B.C., bearing types which continue to the early part of the fine period. These coins are chiefly hemidrachms on the Æginetan system, of which the usual types are, for the obverse, Jupiter Atrophorus seated, the eagle usually represented as if flying from his hand; and for the reverse, a female head. Of a later time, from about the age of Alexander, there are coins with, on the obverse, the head of Jupiter, and on the reverse Pan seated. These form part of the general currency which followed that of Alexander, and was most prevalent under the Achæan League. As they have everywhere a maximum weight of about 40 grains, it is probable that they were equal to low Æginetan hemidrachms, as well as to Attic tetrobola similarly debased; and from their generally having come into use where the system of the former had obtained, they were probably considered as related to it, although actually Attic tetrobola. In Crete, however, the Æginetan standard was supplanted by the Attic, and the same must have been the case in Bœotia, although there no pieces of the later issue above the weight of Attic tetrobola seem to have been common. The coins of Heræa are interesting. They commence at a very remote period, and last to the time of good art. The types of the oldest are, for the obverse, a female head veiled, probably that of Juno, in an extremely archaic style; and for the reverse, the retrograde inscription $\text{A}\Sigma\text{A}$, between two horizontal ornamented borders. These and the other archaic coins are hemidrachms, and a smaller piece, on the Æginetan standard. The antiquity of Mantinea is, in like manner, attested by its money. The silver coins of a very early time have on the obverse a bear, representing Callisto, the mother of Arcas, and on the reverse three acorns in a triangular incuse depression. Others, of a later time, have on the one side an acorn, and on the other the letter M. As to the type of the bear, it may be observed that Callisto was particularly honoured here;¹ and as to that of the acorn, that its occurrence shows that the prominence given to this fruit in the myths relating to Arcadia must be due to a primordial nature-worship, and not to its having been supposed to have been the food of the earliest inhabitants. The silver coins of Megalopolis are important, since we know the city to have been founded B.C. 370. The types are the same as those of the coins of the Arcadians of the same period, the obverse bearing the head of Jupiter, and the reverse Pan seated.² The silver coins of Pheneus must be noticed to be of fine work. The last Arcadian town of the money of which we shall speak is Stymphalus. The finest coin attributed to this place is a magnificent didrachm on the Æginetan standard. The obverse bears the head of Diana laureate, and the reverse Hercules striking with his club. This coin, although of great beauty, is not of the highest style. The head is not sufficiently simple in its treatment, being too rich in the details. The other design also errs in a want of meaning. When Hercules is represented shooting, there is no need to portray the object which he attacks; but when he uses his club, there is a defect if we do not see what he is about to strike. Mr Burgon thinks this piece must be of a city of the same name in Crete, as yet unknown to us from any other source. Not alone is the style of the coin remarkably Cretan, and even the mechanical execution, but the very same types occur on Æginetan didrachms of Chersonesus of Crete. Yet Diana and Hercules were both worshipped in the Arcadian city. The smaller silver coins are undoubtedly of that place. They have on the one side the head of Hercules, and on the other, the head and neck of a Stymphalian bird, most resembling those of a vulture. There were representations of these birds in the temple of Diana at Stymphalus.³ The series of Tegea can scarcely be considered as important, but three of the reverse-types of its copper coins are very interesting. Two of these relate to the story that Minerva gave a jar containing the hair of Medusa to her priestess Sterope, daughter of Cepheus, in order that she might terrify the Argives should they attack Tegea during the absence of Cepheus, when Hercules desired his aid in an expedition against Sparta. The third represents a hind suckling the infant Telephus.

The coins of Crete bear witness to its ancient wealth. Silver Crete must have been abundant, whence, except it were anciently found

¹ Paus. Arc. 3, 9, 35, 36.

² Colonel Leake (*Num. Hel.*, Eur. Gr., p. 72) supposes that the later silver coins of Arcadia were struck at Megalopolis; and this would explain the identity of their types with those of the coins of this place.

³ Paus. Arc. 22.

Greek
Coins.

in the island (and modern researches there have not yet detected any traces of this metal, much less of its former working), we must suppose an extensive and active commerce. The period over which the autonomous silver coins range extends from about the latter part of the sixth century B.C. to the beginning of the Roman rule. The autonomous copper coinage belongs only to the latter part of this period, and gold money has not been found. The imperial coins are not numerous. The types have a very local character, which connects them with early Greek mythology. Neptune, Jupiter, Juno, Hercules, and the local goddess Britomartis, identified with Artemis, are among the principal divinities. Subjects connected with the myths of Europa and that of the Minotaur also occur. Many series have evident reference to the primæval nature-worship. The art of the silver coins of Crete is well deserving of study. In general it is at first rude, and suddenly attains excellence. In its perfection it stands by itself, as wholly distinct from that of any other class of Greek money. In essential excellence it is inferior to no other style, but it errs in a want of fitness, necessarily arising from its intensely pictorial character. The perception of beauty which it displays is very great, although in female heads there is too much richness. The figures, the animal forms, and the trees are drawn with the most admirable truth and freedom, and, notwithstanding, often in very low relief for Greek coins. The pictorial character of this art is shown not alone in the choice of subjects, but in the extremely natural mode in which they are treated, with a constant preference for perspective, without in either case a regard for the form or surface of the coin. Thus, as examples of Greek art, the finest Cretan pieces are of the highest value; but as examples of that art as applied to coins, they are to be consulted with great caution. The standard of the older silver coins, comprising all those of fine style, is Æginetan; and the coins show a considerable lowering of weight. The later coins follow the Attic talent. Judging from their art, none of the older class can be much more recent than B.C. 370, nor any of the later, much earlier than B.C. 320. One thing is certain, that there is a gap between the coins of the two systems which corresponds very well to the reign of Alexander, some of whose coins may be ascribed, on very probable grounds, to Cretan cities.

Of the island of Crete, generally, there are Roman silver coins of the earlier emperors, some of which are of fine work for the period. The inscriptions are either in Latin, or partly in Latin and partly in Greek. In the autonomous civic series there are didrachms of Aptera, called on its money Aptara. The obverse bears a female head wearing a tiara, and the reverse a warrior before a sacred tree.¹ Of Chersonesus, the port of Lycus, called on the coins Chersonasus, there are didrachms of fine style, and sometimes of fine work also. The obverse has a head of Diana Britomartis, who had a temple here;² and the reverse bears either Apollo with his lyre, or Hercules striking with his club. The pieces with the latter reverse are essentially identical with the fine coin hitherto attributed to the Arcadian Stymphalus which we have lately noticed. The series of silver coins of Cnossus is of great interest and beauty. This city is said to have been the capital of the ancient Cretan kings, and its coins show that it must have been a wealthy place. The oldest coins are of a very archaic style, and probably anterior in time to the expedition of Xerxes, and certainly not later. One of these, a didrachm, has on the obverse the Minotaur, portrayed as a man with apparently a bull's head, kneeling on one knee; and on the reverse the Labyrinth, represented by an intricate pattern. Another didrachm, of about the same time, has on the one side the Minotaur, who has here undoubtedly a bull's head, and on the other a head, which appears to be that of a female, within a labyrinthine border. The head, which is probably that of Ariadne, being put for a person, and the border for the Labyrinth, are instances of archaic feeling. The antiquity of these coins disproves the supposition that the Labyrinth was an invention of the later poets, as there is no mention of it by Homer, Hesiod, or Herodotus; a supposition which has led to the conjecture that the idea is of Egyptian origin, and fixed to this place on account of the natural excavations in its neighbourhood.³ The coins show that the myth is older than Herodotus; and it may be observed that the Egyptian Labyrinth, both from the evidence of ancient writers and that of its lately-discovered remains, does not appear to have been what is generally understood by a labyrinth. Further, it is doubtful if Homer do not in one place allude to the Cretan Labyrinth.⁴ Of the early part of the time of fine work are didrachms with, on the obverse, the

head of Proserpine, and on the reverse the head of a bull, for the Minotaur, in a labyrinthine border, or else only a conventional pattern for the Labyrinth. One of these is, on the obverse, in excellent style. These are succeeded by coins of the most beautiful design and execution. They have on the obverse a head of Juno wearing a tiara, and apparently represented as young; and on the reverse the Labyrinth, which here has a rectangular form, and is a maze. The head is of great beauty; its youthful and soft character is probably an effect of Cretan art, but it may refer to the tale that Juno was married near this town.⁵ The didrachm and drachm of these types are known. Of a later time there are tetradrachms on the Attic standard, with, on the one side, the head of Apollo, and on the other the Labyrinth, represented of a circular form; or the head of Jupiter, and the rectangular form of the Labyrinth. There are interesting coins of Cydonia. Their types constantly refer to the myth of Cydon, son of Apollo by Acaëdis, daughter of Minos. The money of Eleuthernæ must also be mentioned.

Gortys, or Gortyna, is represented by most remarkable coins, which generally allude to the myth of Europa. Didrachms of about B.C. 500 have on the obverse Europa carried by the bull, and on the reverse a lion's scalp, in linear and incuse squares. Colonel Leake describes one belonging to Gen. Fox, with nearly this general type, bearing on the reverse a retrograde inscription in archaic characters, ΓΟΡΤΥΝΟΣ ΤΟ ΣΑΙΜΑ[ΣΗΜΑ],⁶ where *σημα* probably means "badge" or "ensign," and not "type;" for the last rendering would not be in accordance with the principles of the inscriptions of Greek coins. These pieces are followed by a remarkably fine class of spread Æginetan didrachms, the types of which relate to the myth of Europa. The best are of the early part of the period of good art, at the time at which perfect skill of handling had been attained. These have on the obverse Europa seated in a pensive attitude on the trunk of a tree, doubtless the sacred plane at Gortyna which was said never to shed its leaves, mentioned by Pliny;⁷ and on the reverse a bull suddenly turning his head, as if stung by a fly. Nothing in Greek art exceeds the skill and beauty of these designs. The truth with which the tree is sketched, and the graceful position of the forlorn Europa, are as much to be admired as the fidelity with which the bull is drawn, even when foreshortened, sharply turning his head, with his tongue out, and his tail raised. These designs, beautiful in themselves, are strikingly deficient in fitness, and afford equally strong illustrations of the excellencies and the one great fault of the art of Cretan coins. Many pieces of the same class are of rude execution, but a fine style is evident in all. There is a tetradrachm with the types of the late Athenian ones, from which it differs only in the name, and in having the badge of a butting bull. The coins of Hierapytna are chiefly remarkable for bearing the representation of a date-palm. Of Itanus there are fine early pieces, and others of the best period. Lyttus, as its name is written on the coins in the Cretan form, instead of Lycus, is represented by many silver coins, chiefly archaic Æginetan didrachms, having on the obverse a flying eagle, and on the reverse a boar's head.

The coins of Phæstus form an interesting series. Among the didrachms are some of admirable work, with, on the obverse, Hercules slaying the Hydra with his club, and on the reverse a bull, excellently drawn. Others, also of fine work, have on the one side Hercules seated on the ground, and on the other a bull within a wreath. The most remarkable coins of Phæstus are, however, those that bear representations of Talos, the man of brass, said to have been made by Vulcan. One of these is an Æginetan didrachm, on which he is portrayed as a winged youth, naked, bearing in each hand a stone, and in a combatant attitude. This figure is accompanied by his name. A similar design is seen on a copper coin. The reader will recollect the accounts which ancient writers give of Talos, and especially that of Apollonius Rhodius (*Argonaut.* iv., 1638, *et seq.*), who relates that he prevented the Argonauts from landing in Crete by hurling stones at them, until he was destroyed by the artifice of Medea. These coins afford important illustration to such scanty and less authoritative notices, and have the advantage, as usual, of addressing us by representation and not by description. Instances of this kind show convincingly the great value of numismatic knowledge in the study of Greek mythology. Of Polyrrhenium, or Polyrrhenia,⁸ there are many coins; the early ones are fine, and should rather be called of the people than of the place, since it is said that at the period to which they undoubtedly belong the city was not built, and the Polyrrhenians dwelt in villages,

Greek
Coins.

by which we can scarcely understand a straggling and unwall'd town.¹ There are interesting coins of Priantus and Rhaucus, both with representations of Neptune. Of Sybrita, or Sybritia, we must notice a didrachm of the finest work, bearing on the obverse Bacchus or a bacchic figure, with a thyrsus carried by a panther, and on the reverse Hercules drawing on his right buskin.

Eubœa.

The coins of Eubœa are plentiful, but their types are not very various. All, however early, are on the Attic standard, and no numismatic indication of a distinct Euboic talent has yet been discovered. Of Eubœa generally, silver and copper coins are known. The former are of the early part, and the rest of the period of good art, but principally of the latter. The obverse has a female head, probably of Venus, and the reverse, the head of a sacrificial bull. Carystus is represented by early didrachms with, on the one side, a cow suckling a calf, as at Dyrrhachium, and on the other a cock; and by later pieces with the head of Hercules bearded, in the lion's skin, and a palm-tree or other device. Of Chalcis there are drachms with the head which is probably that of Venus, and an eagle destroying a serpent, some of which are fine, although not very remarkable for their art. There is an early tetradrachm of Eretria, bearing on the obverse a bull as if stung by a fly, and with a bird standing on his back, and on the reverse a cuttle-fish. Among the later coins no very fine pieces are found. Of Histiaea there are many small silver coins, which appear to be drachms and tetrobols. The obverse-type is, as we think, the head of a bacchic female (for it can scarcely be of the androgynous Bacchus), and is sometimes very beautiful; and the reverse-type is a female seated on a prow, and holding a mast. Most of these coins are of the fine period, but some are late. In the copper series there are also pieces of good style.

Ceos, &c.

Among the other islands classed after Eubœa, Ceos is especially worthy of note. There are coins which have the name of the people in general, and others of the cities of Carthæa, Coresus or Coresia, and Iulis. The silver money of Coresus is wholly of a very early time, for we must assign it to the sixth and seventh centuries B.C., carrying its oldest pieces as far back as near the commencement of Greek coinage. The weight is Æginetan; and there are didrachms and smaller coins. The usual obverse-type is a cuttle-fish and dolphin, and the reverse bears an incuse pattern. Of the coins of Melos the common obverse-type is a fruit, probably a pomegranate. Those who expect, from the excellence of the works of art that have been found in this island, a corresponding beauty in its coinage, will be disappointed, as at Athens. Naxos is represented by early Æginetan didrachms and coins of the fine period, the latter being chiefly copper pieces of remarkably delicate and good work. The types are bacchic. Of Paros the silver money is plentiful, but not very fine; it consists chiefly of Attic didrachms. There are very early Æginetan didrachms of Siphnos, and smaller archaic coins. Some of the copper pieces are of the best period, and very fine. Of Tenos there are silver coins of the good time, but of poor work. The head of the bearded Jupiter Ammon occurs on tetradrachms following the Attic standard, and on smaller pieces, that of the young Ammon, laureate as well as horned, which shows the reasonableness of concluding that the two representations are of the same divinity.

Pontus, &c.

The coinage of Asia commences with that of Asia Minor. The first provinces are Bosphorus and Colchis, the coins of the cities of which are few and unimportant. The coins of the cities of Pontus are more numerous, and although none of them are archaic or deserve to be characterized as fine, the style of some, both of silver and of copper, is not bad. The general series is of copper pieces, which are sometimes large and usually thick, and are of more careful work than those of Greece Proper. The only place meriting special notice is Amisus, which alone of the cities of Pontus seems to have issued autonomous silver coins. These were continued under the emperors in the form of Greek denarii, that is, Roman denarii with Greek inscriptions. The common subjects of the copper money of this place relate to the myth of Perseus and Medusa. The series of the kings of Pontus and Bosphorus has, as its first interesting coins, those of the famous Mithradates VI., king of Pontus, of whom there are staters and tetradrachms. The portrait on the best tetradrachms is extremely fine, and, as a portrait, scarcely excelled in the whole class of Greek coins. Even as a design it has great merits; and this is the more remarkable if we consider the low period at which it was struck. The treatment of the hair has been well explained by the supposition that the head was copied from a statue in which the king, who is said to have been a very skilful rider and charioteer,² was represented driving; an opinion which derives some support from the apparent allusion by Pliny to a work or works of the kind.³ The subsequent coins are not interesting. They are

of the remaining part of the kingdom of Pontus, and of all that of Bosphorus until near its close, probably not very long after the time of Constantine the Great. The gold and silver coins soon became Roman aurei and denarii in their weight. The gold degenerates into electrum, and the silver is supplanted, though later, by potin or other very base metal. These coins bear dates in the Pontic era.

Greek
Coins.

In Paphlagonia we must especially notice the coins of the cities Paphlagonia and Sinope. The silver pieces of the former place bear a female head, in a laureate Phrygian bonnet, probably representing Amastria the founder. On the late copper money the bust of Homer occurs. There are also copper coins of the imperial class. The silver pieces of Sinope are plentiful, and of fair work. There are copper coins of a Pylæmenes, king of Paphlagonia, but it is not known to which of the sovereigns bearing that name they should be assigned. Bithynia is represented by a more important series. Of the country generally there are Roman silver medallions, of the weight of low Attic tridrachms, with Latin inscriptions, and imperial copper pieces with Greek inscriptions. The ordinary silver coins of Chalcedon strikingly resemble, on both sides, the early ones of Byzantium, a circumstance confirmatory of the statement that the two cities were colonized at nearly the same time from Megara. Of Cius, also called Prusias ad Mare, there are fine silver pieces: the latter name occurs on some of those in copper. Hadriani and Hadrianotheræ issued autonomous copper coins. Of Heraclea there are silver coins of good work of the fine period; these are Æginetan didrachms, and smaller pieces apparently on the same standard. The obverse-type is a head of Hercules, either bearded or beardless, in the lion's skin; and the most interesting reverse-type, a female head wearing a tiara on which are three turrets, is probably that of the town personified. Of the tyrants of Heraclea, there are silver coins of Timotheus and Dionysius ruling together, and of Dionysius reigning alone. Of the imperial class, there is a large series of Nicæa, and there are many coins of Nicomedia. The series of Bithynia closes with the money of its kings, consisting of Attic tetradrachms and copper pieces. The tetradrachms bearing the name of Prusias are probably of Prusias I. and II., for there is some difference in the portraits. The copper coins with the same name, some of which are fine, cannot be otherwise classed than to both kings, since we do not know by which of the two they were issued. Of Nicomedes II. and III. there are only tetradrachms.

The fine Greek coinage of Asia may be considered to commence Mysia, with Mysia. Cyzicus is in numismatics a most important city. From it the Cyzicene staters derived their name, which appears to have been used as a general appellation of the electrum staters of the west coast of Asia Minor, although those of Phocæa were distinguished. Some of the known specimens of these coins, as well as of the hectæ, were doubtless struck at Cyzicus; but we have thought it best to group the whole class to which they belong together, until it is more certainly classified. The silver coinage of this town comprises archaic but not very old pieces, and others of early fine work, but of somewhat archaic style, having on the obverse a half-boar, behind which is a fish, and on the reverse a lion's head in profile, within an incuse square. Of the best art there are most beautiful tetradrachms of the Phœnician or Persian talent. The obverse bears a head of Proserpine, with a veil on the back wound round her hair, and in the hair ears of corn. This is an example of the best Greek art, equally simple, delicate, and graceful. Such a union of beauty with breadth and simplicity is very rare, especially in the representation of female heads. Above the head is the inscription ΣΩΤΕΙΑ, which may be compared with ΚΟΡΗ ΣΩΤΕΙΑ ΚΤΖΙΚΗΝΩΝ on a late copper coin, accompanying a head which is probably that of the younger Faustina in the character of Proserpine. The reverse-type of the fine tetradrachms is a lion's head in profile above a fish. These were followed, after a long space, by coins on the Attic weight; for there is a tetradrachm on that standard resembling those of the later Macedonian kings. Some of the autonomous copper coins are fine, but most are of a low period, probably having been issued just before and under the Roman domination. The late pieces are, however, sometimes of good work for their time. There are also many imperial copper coins.

The money of Lampsacus must next be noticed. In gold there are fine staters, adjusted apparently to the standard of the darics rather than to that of the Attic talent; although, from the small difference in weight, this is hard to determine. One is very fine, though not of the highest art, and remarkable for the peculiar style of the design of its obverse. This is the head of a bearded man, with long dishevelled hair, and covered with a conical cap bearing a wreath. It may perhaps be a head of Neptune. The

¹ Strabo, lib. x., cap. 4. As, however, the city built by the Achæans and Lacedæmonians is here described as strong, it is possible that the villages which it supplanted really formed a straggling town without walls.

² Appian. *Mithr.* § 112.

³ Plin. *Hist. Nat.*, lib. xxxiii., § 54.

Greek Coins.

reverse has the fore-part of a winged horse, the wing being curled, and the body terminating in what seems to be a kind of fin, so that the monster would appear to be a sea-horse. The old silver coins have on the obverse a Janus-like combination of two female heads. Of the good period there are some small pieces; and there is also an Attic tetradrachm of late time, showing the abandonment of the old standard, which was probably Phœnician. The autonomous copper money is not very important. Of Parium there are silver coins of the early fine period, and of rather archaic style. Some copper pieces of good time are remarkable for bearing an altar in perspective, such objects being scarcely ever thus represented until a much later period.

The coins of the great city of Pergamus or Pergamum are chiefly of a late time. There are, indeed, gold and silver pieces of the good period, the former being very rare; but the most numerous silver coins are cistophori, and therefore late. The cistophorus, as we have already shown, is in weight an Attic tridrachm, but it probably came, through the depreciation of the Phœnician tetradrachms of Rhodes and other places, to be considered a tetradrachm, and thus the half and quarter of it were struck, although apparently in no great numbers. All the cistophori are of the kingdom of Pergamus, which afterwards became the Roman province Asia. The oldest were most probably issued under the kings, but the later are of the Roman rule, and we find on them the names of proconsuls or prætors of Asia, and of proconsuls of Cilicia, from the time at which Phrygia was given to that province. Thus the name of M. Tullius Cicero, as proconsul, occurs on a cistophorus of Apamea of Phrygia, and, with the title "Imperator," on one of Laodicea in the same country, the latter coin illustrating an event narrated by the orator.¹ The obverse-type of these pieces is the *cista mystica*, a basket from which a serpent issues, all within a wreath of ivy; and the reverse-type, two serpents, partly intertwined, and rising on either side of a bow-case, or sometimes, but rarely, of some other object. These proper cistophori are succeeded by coins of the time of the triumvirate of Mark Antony and his colleagues, with a Roman head or heads on the obverse, and serpents on either side of the cista, and of some other object, on the reverse; and these, again, are followed by the so-called imperial silver medallions of Asia, which are of the weight of cistophori. These last have on the obverse either the head of an emperor or that of an empress, and on the reverse various designs, and are of fine work for the period. The earliest are of Augustus, and the latest of Domitian.² The copper pieces of Pergamus are numerous, both of the autonomous and of the imperial class, the latter comprising some medallions. The principal coins of the kings of Pergamus are Attic tetradrachms, with, on the obverse, a laureate head, believed to be that of the first king, Phileterus, and on the reverse a seated Minerva. The portrait is often very fine, when it must be considered to be one of the best Greek portraits, and an excellent example of the work of the time. The reverse is probably taken from that of the common tetradrachms of Lysimachus, from whom Phileterus revolted. Although the inscription of the reverse is always ΦΙΛΕΤΑΙΡΟΥ, a monogram or letter sometimes points out the king by whom a particular coin was issued. Besides these tetradrachms, there are copper coins, which, however, are unimportant.

The Troad.

The coinage of the Troad is chiefly interesting from its reference, in its later pieces, to the Trojan War, and the manner in which it thus illustrates the Iliad. We must recollect, however, that this kind of evidence on very late coins cannot be safely held to be independent, except where the type is of an indisputably religious character, and also that, at the Roman time, and a period somewhat earlier, this character is not constant. Hence we must not hastily conclude that the coins show that there was a local tradition of the great contest, nor that they prove its heroes to be mythical. Of Abydos there are silver coins of the early part of the good period, which seem to be adjusted to the Phœnician talent. The drachms have on the obverse an anchor, to which a craw-fish is about to cling; and on the reverse a head of Medusa, with the serpents, which are not usually represented on the coins. There are Attic tetradrachms of a late time, noticeable for their strange fabric, which gives them the appearance of cast coins, and renders them suspicious to those who are unaware of this peculiarity. Alexandria is represented by late Attic tetradrachms, having on the one side a head of Apollo, and on the other, Apollo advancing with bow and arrow, and the inscription ΑΠΟΛΛΩΝΟΣ ΣΜΙΘΕΩΣ.

ΑΑΞΑΝΑΡΕΩΝ, &c. There are later autonomous and imperial coins, in copper, of the Roman colonia. Of Ilium there are likewise late Attic tetradrachms of coarse work, bearing on the obverse the head of Minerva, and on the reverse the same goddess advancing, holding in her right hand a spear, which rests on her shoulder, and in her left hand a distaff, with the inscription ΑΘΗΝΑΣ ΙΛΙΑΔΟΣ, &c. One of the autonomous copper pieces has on the obverse Hector in a combatant attitude, with his name ΕΚΤΩΡ, and on the reverse the wolf and twins, showing that it is of the Roman period. On another copper coin Aeneas is represented carrying Anchises, and leading Ascanius. There are also many imperial copper pieces of this place. Of Scepis, which is said to have been the capital of a Dardanian kingdom for a long period between the fall of Troy and the age of Alexander,³ there are archaic silver coins; and some of its copper money is of good style. Sigeum was for a great length of time a dependency of Athens; and the common types of its silver coins are accordingly Athenian, although the style of art is different. The island of Tenedos is represented by very early coins, and others of the fine and late periods. The usual obverse-type of all the silver pieces is a Janus-like combination of two heads, probably those of Jupiter and Juno; and the usual reverse-type of all but the oldest is a two-headed axe.⁴ The weight seems to be always Attic.

In *Æolis* we may notice that some of the coins of *Ægæ* are of a *Æolis*. very early time, and that the principal type, the head and neck, or fore-part of a goat, is probably connected with the name. The town of *Cyme* is represented by an important series of silver coins. A few of these are early, but most are fine late Attic tetradrachms, probably first struck not very long after Alexander's time, and perhaps issued for about a hundred years. On the obverse is a female head, perhaps that of *Diana*, bound with a narrow fillet: the style has some purity and vigour, though yet far inferior to that of the best Greek coins, and thus shows the vitality of art in *Asia Minor*. The reverse-type is a horse within a wreath of laurel. There are also examples of fair work among the copper coins. Of *Myrina* there are Attic tetradrachms like those of *Cyme*, and of about the same period. The obverse-type, which is a laureate head of *Apollo*, is in a vigorous style. The imperial coins of *Æolis* are not very numerous.

The coinage of Lesbos is remarkable for the base material of Lesbos, what we may consider, as a class, to be its oldest pieces. These, although at first heavier, probably represent Æginetan didrachms and divisions, their original weight having been determined on the same principle as that which regulated the weight of the electrum coins of Asia Minor. They are doubtless of the different cities of the island, although it is difficult to attribute most of them. Certain of these early base silver coins, with, on the obverse, two boars' heads facing one another, and on the reverse an irregular incuse square, must be classed to Antissa, as Mr Burgon has determined, since one bears the letters AN in monogram. To Methymna may perhaps be assigned a coin of the kind just noticed, but there is also a silver one of very archaic style, which is, if not anterior to it, at least of the same time. Of a later period there are fine coins of this town. Among the copper pieces we must not pass by one already mentioned, on which Arion and the dolphin are represented. The weight of the pure silver coins of Methymna seems to be always Attic. Mytilene appears to have struck electrum coins, for hectæ are assigned to it, one of which bears the letters ÆE. It must be remembered that this was the chief town of the island, and, as Col. Leake supposes, Homer's *Δίαβαρ Ἰστέμειον*. There are early base coins of this place, and silver of the fine period. The standard seems to be Æginetan. The copper pieces are numerous, and the earliest are of fair style. The very late are interesting, as bearing the names and portraits of benefactors. Mytilene is thus shown to have honoured such persons as heroes or heroines; and one, Theophanes, the friend of Pompey, from whom he obtained for this city, his native place, the privileges of a free state, is indeed even called a god; while Archedamia, probably his wife, is styled a goddess. The imperial coins of Mytilene may also be mentioned: they comprise medallions. There are beautiful copper pieces of Pyrrha, of the good period.

The electrum coins of Asia Minor may be best placed between **Electrum** **coins of** **Asia** **Minor.** **Æolis** and **Ionian**, in the opinion of Mr Burgon, since this position is about the centre of their geographical range. They form a most interesting class, whether we consider the antiquity of the earliest, or the admirable style of the designs of a great proportion, or their

Greek
Coins.

general importance in reference to Greek mythology. As to their art, it may be truly said that it is impossible to form a fair opinion of the artistic excellence of the coins of the west of Asia Minor without a knowledge of these, which make up the majority of the most carefully-executed specimens struck during the best period. The earliest electrum coins have the appearance of a greater antiquity than any in the whole Greek series; and thus explain the remark of Herodotus, that the Lydians, as far as he knew (for he does not here omit his characteristic cautious mode of expression), were the first who struck money. Although perhaps the first coins may have been struck in Ægina, and others soon afterwards elsewhere in Greece, and this useful invention speedily adopted in Asia, it seems more probable that it was of Asiatic origin; and it should be remembered that the part of Asia to which the electrum class belongs was at this early period subject to the Lydian kings. The oldest pieces are staters and smaller coins, with rude and seemingly unmeaning incuse stamps on the obverse, and on the reverse a mere mark of the rough surface of the anvil. These are followed by coins with a rude design on the obverse, and irregular incuse stamps in a square on the reverse. After a time the art of the designs on the obverse improves, and the reverse is occupied by a quadripartite incuse square, of which each of the divisions is in a different plane. There are many staters and hectæ of this class, which we may call the later archaic, to distinguish it from the older class which precedes it. To the same group must be assigned some hectæ struck towards the close of its period, which are remarkable for having a second and incuse design on the reverse, differing from that on the obverse. The electrum coins of the best period commence with such as are slightly archaic. These have the quadripartite incuse reverse, which is, as far as we know, the invariable reverse of the staters of this whole period. These staters are of pure and excellent style in their designs. The hectæ are unexcelled for breadth and purity of style, combined with the greatest beauty and refinement. They present a most interesting series of heads of Greek divinities. The latest show a slight decline in their style.

Ionia.

In Ionia we must first notice the town of Clazomenæ, the earlier silver pieces of which bear the fore-part of a winged boar. Among the coins issued at a later time, we must notice three examples which worthily support the character we have given the artists of Asiatic Greece. These are, a gold coin of the weight of the third of an Attic tetradrachm, and two silver Attic tetradrachms. The obverse-type of all is a head of Apollo facing, and the reverse-type a swan. The age is about the middle or latter part of the fifth century B.C.; and the head is in the very best Greek style, the swan being not so finely executed. The former is slightly better on the gold coin, where it has a simple grandeur and beauty that gives it a place among the first monuments of Greek art. On the two tetradrachms the head is but little inferior; and it is noticeable that the artist, proud of his work, has inscribed on both (for they are by the same hand, though from different dies) "Theodotus made this" (ΘΕΟΔΟΤΟΣ ΕΠΟΙΕΙ). There is a tetradrachm, doubtless later, on which the head of Apollo shows an ornate and mannered style. Some of the copper coins are of the good time, and well executed.

Passing Colophon, of which there are archaic coins and others of the fine period, we reach Ephesus. The early silver pieces of this town, which are not of a very remote period, have on the one side a bee, and on the other usually an incuse square, rudely divided into four parts. The most important of the older coins of the fine period are tetradrachms of the Phœnician talent, bearing on the obverse a bee, and on the reverse a date-palm and the forepart of a stag. The principal later coins of the same period are didrachms of a lower weight, and in time a little before the expedition of Alexander. They bear on the one side the bust of Diana, in a beautiful style, but not the finest; and on the other the fore-part of a stag. Of a still lower time there are many cistophori. Some of the autonomous copper pieces display a good style of art. There is a large imperial series, including some coins of silver. Of the latter metal certain are of especial interest, since they bear, although they are evidently of Roman weight, inscriptions stating them to be drachms and didrachms. These are followed by Roman denarii of fine work, with Latin inscriptions. The imperial copper money also presents specimens of good art for the period. There are coins in both silver and copper of Ephesus with the name of Arsinoë, which the city took from the wife of Lysimachus, and bore only during his life. They have the portrait of Arsinoë, which may be compared with that on her Egyptian coins as wife of Ptolemy Philadelphus.¹ The money of Erythræ bears types connected with Hercules. Some of its silver coins, on the Phœnician standard, are of good style; and the autonomous copper pieces are noticeable for the great number of magistrates' names which they bear, indicating the long period during which they were issued. On

Greek
Coins.

the coins of Magnesia are subjects connected with the River Mæander. Thus the earlier silver pieces, which have on the obverse an armed horseman galloping, bear on the reverse a humped bull butting, within a circular meander, or upon a straight device of the same kind; so that there seems to be a double symbolic representation of the river. There is also a fine spread Attic tetradrachm, of late time, but of fair work, like those of Cyme; and having on the obverse the bust of Diana, and on the reverse Apollo standing on a meander. Of Miletus there are a few archaic silver coins on the Attic standard, with, on the one side, a lion's head and fore-leg, and on the other a conventional star in an incuse square. The later pieces, which appear mainly to follow the Phœnician standard, are of good and sometimes excellent work. Their obverse-type is a head of Apollo, and their reverse-type a lion looking back at a star. The silver coins of Phocæa are very early, and have on their obverse a seal, reminding us of the derivation of the name of the place. The copper coins are much later, and some of them are in a good style. No early silver coins of Smyrna are known, the pieces in this metal being late Attic tetradrachms, with, on the obverse, a female turreted head, probably that of Cybele, and on the reverse a lion or a monogram, within a wreath of oak. In copper there is a large series, both of the autonomous and of the imperial class. Some coins of the former kind are of fair work. Certain of them have on the obverse a figure of Homer seated; and it was doubtless copper money of Smyrna of this sort which Strabo mentions as bearing the name 'Ομήριον. Other autonomous copper coins bear on the obverse the head of Mithradates VI., and were doubtless struck when he held the place. The imperial class comprises fine pieces, with portraits of great beauty and merit, and otherwise of good work. Historically the most interesting are those which bear the name of a Vespasianus Junior (Ἰσώριος), supposed to be a prince of the Flavian family not otherwise known to us. Of Teos there are archaic Æginetan didrachms, bearing on the one side a seated gryphon with curled wings, and on the other a quadripartite incuse square. There are later coins of the earliest good work, and others of subsequent times.

Chios and Samos, islands of Ionia, are represented by interesting Chios and coins. Of the former there are archaic silver pieces, but the Samos. greater number of its coins are of the early fine period. The obverse-type is a seated sphinx with curled wing, and an amphora upon a slightly-raised surface like a shield; and the reverse bears an irregular incuse square of four divisions. The weight is Phœnician. There are later coins in silver, and many autonomous and imperial copper pieces. Some autonomous copper pieces of the Roman period have the value inscribed, thus ACCAPION HMTET, [sic.] ACCAPIA AYO, ACCAPIA TPIA, and also OBOAOC, the latter being properly the name of a Greek silver coin. The coins of Samos are on the Phœnician standard. There are numerous tetradrachms, some early, and many of the good period. Their common obverse-type is a lion's scalp; and the early coins have on the reverse the head and neck of a bull, the later, the fore-part. Some of the smaller silver pieces are supposed from their types to have been issued at a time when Samos and Clazomenæ were in alliance.

The autonomous civic coinage of Caria is generally poor in art, Caria. and even inclining to barbarism. Of the imperial class there are coins of many cities, but no one very large series. The autonomous money of Cnidus, of which the silver follows the Phœnician system, deserves especial mention. The early coins have on the obverse the head and fore-leg of a lion, and on the reverse the head of Venus. The same types continue, but during the time of good art they change places. There are other silver coins of Cnidus, with, on the one side, a Rhodian type, the head of Apollo facing, and on the other the Cnidian head and fore-leg of the lion. These indicate a Rhodian alliance or domination. The money of Halicarnassus includes some silver pieces of the good period. Of Iasus there are silver coins of good but not the best style, having on the obverse the head of Apollo, and on the reverse a youth swimming beside a dolphin which he holds—a type reminding one of the well-known didrachms of Tarentum. Of Myndus there are silver pieces, with, on the obverse, the head of Jupiter, and on the reverse an Egyptian divinity's plumed head-dress. The coins of Nysa, of Stratonicea, and of Tripolis may also be mentioned. The money of the kings of Caria is worthy of note. The weight is Phœnician. There are tetradrachms, didrachms, and drachms, having for their obverse-type a fine head of Apollo, laureate, facing; and for the reverse-type a standing figure of the Carian Jupiter holding a two-headed axe and sceptre. These pieces are of Mausolus or Maussolus, of Idrieus or Hidrieus, and of Pixodarus.

First of the islands of Caria, Calymna should be noticed. The Calymna early silver coins are extremely barbarous, but the later are in a good style. The obverse bears a helmeted male head, in the earlier

¹ See a paper by Mr Borrell of Smyrna (*Num. Chron.*, vol. ii., p. 171, et seq.)

Greek
Coins.

Cos.

pieces bearded, and in the later, beardless; and the reverse, a lyre. Cos affords an important series. The standard of the silver pieces appears to be Phœnician, but if so, the weight of the earliest is very heavy. The oldest tetradrachms have remarkable types: that of the obverse represents a naked male figure dancing and beating a tambourine before the tripod of Apollo, and the reverse is occupied by an irregular incuse square, divided diagonally, and having a crab in the centre. The obverse-type is in a very fine late archaic style. Among the later coins we must notice, as the most beautiful, although not severe in its treatment, one with, on the obverse, a head of Hercules bearded, and on the reverse a head of Ceres veiled. There are also small pieces of a subsequent time, which bear on the one side a head of Æsculapius, resembling that of Jupiter, and on the other a serpent. Many copper coins also bear types relating to this divinity. The imperial money is insignificant.

Rhodes.

The island of Rhodes takes an important place in numismatics. In Homer's time, three cities, Lindus, Ialysus, and Camirus, divided its territories between them. After having existed several centuries, these cities united to found Rhodes, and ceased to possess separate laws. Strabo places this event in the course of the Peloponnesian War (*κατὰ τὰ Πελοποννησιακά*), and gives another indication of its date when he says that the architect employed was Hippodamus of Miletus, who built the Piræus of Athens, for the latter work was executed about B.C. 475. It may therefore be supposed that Rhodes was founded not very long, perhaps as much as twenty years, before the Peloponnesian War, which began B.C. 431. These particulars entirely agree with the numismatic evidence. The coins of the three cities, if we include those attributed to Astyra, are generally of archaic fabric, and in no case late; while those of Rhodes do not in style reach earlier than the middle of the fifth century B.C. The coins of Camirus and those of Ialysus, the latter seeming always to commemorate alliances, are worthy of careful study. Of Rhodes there are gold staters of Attic weight, and smaller pieces, all of a low period. The silver coins form a large series. The pieces struck before Alexander's expedition may be considered as generally of the good period, although some of them are archaic; and those issued after his reign may be assigned to the time of decline. During that reign his regular coinage was struck at this city. The obverse bears a head of Apollo, facing in the large coins, and usually in profile in the small. The earlier are chiefly to be distinguished by the facing head of Apollo being bare, and the later, by its being radiate. On the reverse is a rose, almost always represented in a side view, but sometimes as seen from above. After a very careful examination of many examples, we are firmly convinced that this is nothing but a single rose. It has been suggested that it is a pomegranate flower (*βαλάνουρος*); but the coins seem to us absolutely to overthrow this theory, although supported by the opinion of Colonel Leake. No doubt there is a certain degree of conventional treatment in the representation, but not enough to render its meaning in any degree doubtful. Some of these coins are fine, although most of them show, in the head, a degree of harshness. The weight is Phœnician, and becomes very low. The autonomous copper coins are similar to the silver; a few are fine, and some are very large. Those of the imperial class are unimportant.

Lycia.

Entering Lycia, we are in a more Asiatic region than any through which we have passed. The earlier coins have a peculiarly local character in most instances, and are no doubt of the Persian domination. It seems probable that their issue ceased somewhat before Alexander's expedition, for we can scarcely bring the latest quite as low as that event. There can be no question that, here as elsewhere, a Greek coinage was then introduced, first struck by Alexander, and afterwards by the cities. The earlier coins are principally of silver, but copper pieces occur. Some of the former have a very archaic aspect; and the style of all would be called archaic elsewhere, but here the eastern character of the devices must be taken into account. The types present a union of Greek and oriental designs, the most common of which is one probably of the latter class—the so-called triquetra, an object resembling a ring to which three hooks are attached. A man-headed bull with curled wings is also to be noticed. The inscriptions are in Lycian characters, except in the case of the early pieces of Phœlis, which have Greek letters. The coins with Lycian inscriptions have not been satisfactorily attributed. The standard is probably Phœnician, but this cannot be regarded as certain. Sir Charles Fellows has published a list of all the specimens of this class known to him, with engravings of the greater number.¹ The later coins, or such as were struck after Alexander's time, are of inferior interest to those which we have just noticed. The common types are, for the obverse the head of Apollo, frequently in rather an androgynous character, and for

the reverse, a lyre in a shallow incuse square. These occur on small silver coins of the cities Cragus, Limyra, Massicytes, Patara, and Phœlis, the earlier coins of the last of which we have already noticed. The imperial pieces of Lycia, in silver and copper, form a very small class.

Greek
Coins.

The older of the autonomous coins of Pamphylia show oriental Pamphylian influence, although this is principally displayed in the weights and lia. inscriptions. The imperial money consists of copper pieces, which are not of great importance. Of Aspendus there is a large series of silver coins. They appear, from their weight, to be double silver darics, equal to two-thirds of the Phœnician tetradrachm. The inscription is in a Pamphylian form, and written in Greek characters. The common coins are generally of the early part of the fine period; they have on the obverse two wrestlers engaged, and on the reverse a slinger discharging a stone, with, in the field, a triquetra formed of three legs, like that represented on coins of Syracuse. The autonomous series of Perga is not important. Of Side there are archaic pieces of the weight of double silver darics. Their obverse-type is a pomegranate fruit (*σίδην*) above or upon a fish. Of a subsequent period are early fine silver coins of the same denomination as the older ones, although lighter. Their obverse-type is Minerva holding an owl or a little Victory, with a pomegranate in the field; and their reverse-type, a male figure sacrificing. They bear an inscription in Sidetan letters, which differ from those on the coins of Aspendus—some being apparently Phœnician, while others are Greek. After these coins are Attic tetradrachms, bearing on the one side the head of Minerva, and on the other a Victory, with a pomegranate in the field. They are very similar to the tetradrachms of Amyntas, King of Galatia.

In Pisidia the only important autonomous series is that of Selge. Pisidia, &c. The principal coins are pieces of the weight of double silver darics. Their types are essentially the same as those of the silver coins of Aspendus, already noticed. On the one side are two wrestlers, and on the other a slinger, who here appears to be Hercules, with a triquetra in the field. The inscription is Greek. The autonomous copper money of Termessus must also be noticed. The imperial coins of Pisidia are not very numerous. Of the cities of Isauria there are only a very few imperial copper coins; and in Lycæonia there are some autonomous pieces of Iconium, and a very scanty imperial series of that and other places. Cilicia has a higher numismatic interest. The autonomous coins display Persian influence, even if we exclude, as of the oriental class, the money of the satraps. The weight is evidently on the Phœnician standard, and the principal denomination is generally what we may term the double silver daric. The imperial coins are not very important. Of Celenderis there are archaic and early fine pieces, of the weight of double silver darics. The older are not of a remote time, and some of them are remarkable for the excellence of their style and execution. The obverse-type is a naked horseman seated sideways, and the reverse-type is a goat crouching forwards. The coins of the good period present no great differences. Of Mallus there are silver coins, which are either partly or wholly Persian in their types. These are of the same denomination as the pieces of Celenderis just noticed. So also are the silver coins of Nagidus, which are of fine or fair style, as well as those of Soli, some of which are very early, but others of the period of good art. The autonomous silver coins of Tarsus bear witness to its ancient wealth. The earlier are on the Phœnician standard, and the chief piece is of the weight of a double silver daric; and the later follow the Attic standard, and the principal denomination is a tetradrachm. The former are of the Persian period, and the latter of that of the Seleucidæ. The inscriptions of these silver coins are Phœnician, and their types have an oriental character. The Phœnician coins having the weight of double darics have on the obverse Baal of Tarsus seated, and on the reverse a lion seizing a stag; and the Attic tetradrachms have the same obverse-type, and the reverse-type of a lion walking. Among the devices of the copper coins is the so-called monument or, incorrectly, tomb of Sardapanalus. The imperial coins include some base silver or potin pieces. The coins of satraps struck at Tarsus should be referred to the Persian series. It may be noticed that there are copper coins of Tarcondimotus and Philopator, kings of Cilicia.

The coins of Cyprus form a small but remarkable series. They Cyprus. do not commence at a very early period, for one of the oldest is struck upon a silver coin of Aspendus, with the types of the wrestlers and slinger. The usual metal is silver. The types frequently refer to the worship of Venus. The inscriptions are in Cyprian characters; but the pieces of one place, if the attribution be right, bear Greek letters, and there is an instance of Phœnician letters on the same coin with Cyprian ones. The art is chiefly remarkable for its oriental character, which gives the coins an

¹ *Coins of Ancient Lycia before the Reign of Alexander, with an Essay on the relative Dates of the Lycian Monuments in the British Museum*, by Sir Charles Fellows, 1855.

Greek
Coins.

archaic appearance that more satisfactory evidence does not corroborate. The denominations appear to be Phœnician, and there is no doubt that the heaviest is of the weight of two silver darics. Pieces having on the obverse a ram lying down, and a reverse, either perfectly plain, or else bearing a ram's head or a kind of *crux ansata*, are assigned by the Duc de Luynes to Amathus, with two exceptions. The coins with the Greek inscription MAP, before alluded to, he attributes to Marium. To Salamis he classes coins of which two types are worthy of note. One of these represents a female seated on or carried by a bull, and the other a figure, apparently also that of a female, carried by a ram. The former type connects the myth of Europa with the worship of the Cyprian Venus and Astarte; and the latter connects these again with the story of Helle, and the recumbent ram on the Cyprian coins with the famous one which bore the Golden Fleece. There are a few copper coins of this class. The Duc de Luynes has published an excellent essay on these coins of Cyprus.¹ A few pieces are known of the kings of Cyprus. Of the Greek imperial class there are base silver and copper pieces of the island generally, on which occurs, in both metals, a remarkable reverse-type representing the famous temple of Venus at Paphos.

Lydia.

The coinage of Lydia is chiefly of copper pieces, the majority of which are either actually imperial or struck during the imperial period. The autonomous copper coins of Blandus may be mentioned, as well as those of Magnesia ad Sipylum. One of the latter place is of the highest interest, from its bearing a fine portrait of Cicero, which is no doubt nearly or quite contemporary. It is of good work, resembling in that respect the Roman money of the earlier emperors. The autonomous copper coins of Philadelphia must also be noticed. Of Sardis there are cistophori, as well as many copper pieces. Some of the latter, of the imperial class, display good work. There are copper coins of Thyatira, both autonomous and imperial, some of the latter being of fine work for the period to which they belong. Tralles is represented by cistophori and by copper coins. There are some uncertain Lydian coins, which were probably struck at Sardis by a Lydian king, perhaps Croesus. They are of both gold and silver, and bear on the obverse the fore-part of a lion facing the fore-part of a bull, as if attacking it, while the reverse is occupied by an incuse square rudely divided into two parts. The gold coins weigh the same as the darics, and the principal silver ones, like the so-called silver darics, one-third less. The type is manifestly of an oriental, if not a Persian character, being only another form of the common one of a lion seizing a bull. It would be hasty, however, to conclude that the coins are of the time following the overthrow of Croesus by Cyrus.

Phrygia.

The coinage of Phrygia is chiefly of the Roman period, and its imperial pieces are numerous and interesting. Of Apamea Cibotus, more anciently Celænæ, there are cistophori and autonomous copper coins, some of which are of a fair style for the late time at which they were struck. The imperial series contains the remarkable pieces which have been supposed to bear a representation of the ark of Noah. These are of Septimius Severus, Macrinus, and Philip Senior, and have on the reverse an ark in the shape of a boat or chest, with two persons either within or near it, and upon it the letters NQE or NQ. It is not reasonable to suppose, as has been frequently done, that these coins directly refer to the Noachian Deluge. It does not seem possible that any Jewish or Christian community would have been able, at the time when these pieces were struck, to fix types of the public money of a pagan town, and it is by no means likely that any local tradition would have preserved the actual name of Noah. The letters which appear at first to be that name may, however, be part of the name of the people, ΑΠΑΜΕΩΝ, or they may have been added by tooling in modern times, but as to this we cannot speak positively, not having seen any of the specimens. In either case the designs would do no more than refer to the story of Deucalion, and so indirectly to the Deluge of Noah. The appellation *καβαρίς* given to the town implies some connection with an ark; and it is very probable that the tradition of a great flood would be stronger in Phrygia than in Greece Proper, from the former country being much nearer the site where the ark must have rested than the latter. There is another coin of Apamea with a remarkable reverse, which we have already described in an earlier place. It is one of Septimius Severus, with the type of Minerva playing on the double pipe. Other pieces also have designs relating to the myth of Marsyas, as one of Hadrian, on which he is represented playing on the double pipe. Of Cibyra there are silver coins of a base style, and copper pieces; and of Hierapolis, copper coins, including some of a fine late style. Laodicea is represented by cistophori and autonomous copper coins, of which last some are of fair style, as one with the bust of M^{arc} or Lunus upon a crescent, wearing a Phrygian bonnet wreathed with laurel. Some

of the early imperial pieces bear fine portraits. On the copper coins of Prymnessus the bust of Midas is represented wearing a Phrygian bonnet.

Greek
Coins.Galatia and
Cappadocia.

The autonomous coinage of the cities of Galatia is very unimportant, and the imperial series is not extensive. There are coins of several kings, of whom the principal one is an Amyntas, believed to be the contemporary of Strabo. The gold money attributed to him is of doubtful authenticity. His silver pieces are light Attic tetradrachms, greatly resembling those of Side. There are imperial copper coins of Galatia generally.—The autonomous civic coinage of Cappadocia is very scanty; but of the imperial class there is one long and interesting series—that of Cæsarea. It comprises silver coins of somewhat base metal. These are of several denominations, of which the basis seems to be a Greek denarius, than which there is a lighter piece as well as heavier ones. They were struck for about 200 years, terminating after the reign of Geta. Among the reverse-types must be noticed a Bactrian camel, and the sacred mountain Argæus. The latter subject is frequent on copper as well as silver coins; and on the former the mountain is sometimes represented as if upon an altar. The money of the kings of Cappadocia is also worthy of note. It consists of silver pieces, which appear to be Attic drachms, and were struck during a period extending from about the last quarter of the third century B.C. to the time when Cappadocia was made a Roman province. The coins bear portraits which are sometimes well executed. There are a few copper pieces of the ancient kingdom of Armenia.

Syria.

The coinage of Syria commences with the series of the Seleucids, which, for the excellence of its portraits, may, as a whole, take the first place in the class of Greek regal money. It comprises a few gold pieces; its silver coins, which are chiefly tetradrachms, are abundant, and there are many copper coins. The reverse-types present no great variety, and are usually of little interest. The weight of both gold and silver coins is Attic, excepting those in the latter metal issued by the Phœnician mints, which, save the earliest pieces of Sidon, which are on the Attic weight, follow the standard of the Ptolemaic coins. Of Seleucus I. there are gold staters. Most of his tetradrachms have the same types as those of Alexander the Great, with sometimes this deviation, that the Jupiter on the reverse holds a Victory instead of an eagle. Some, however, have on the obverse a head, doubtless that of Seleucus, in a close helmet, mainly formed of the skin of a bull's head, with the horn and ear. Other tetradrachms have on the reverse Minerva fighting in a quadriga of elephants, with, in the field, an anchor, the symbol of Seleucus. It is remarkable that, under the next sovereign, Antiochus I., tetradrachms were still struck bearing Alexander's types, but with, in the only example we have seen, the same variation of the reverse-type as in some of the similar coins of Seleucus I. The ordinary tetradrachms bear the king's portrait and Apollo seated on a corymba, a common reverse-type of the earlier Seleucids. The tetradrachms of Antiochus II., Seleucus II., Antiochus Hierax, and Seleucus III., are only interesting for their portraits. Antiochus III., or the Great, struck gold money, for there is an octodrachm, of course on the Attic standard, among his coins. The portrait on the tetradrachms varies according to his age: sometimes it is fine. The tetradrachms of Seleucus IV. need not be noticed, except as having portraits. Those of Antiochus IV. have two types of obverse, both of which are fine heads: one of these is undoubtedly that of this king; the other, which is bearded, may be that of Jupiter, although it has a resemblance to the portrait. The tetradrachms of Antiochus V. and Demetrius I. have portraits. Of Alexander I. there are not only Attic tetradrachms, but also Ptolemaic of Tyre and Berytus, having an eagle on the reverse, the characteristic of the class, plainly showing its Egyptian origin. A tetradrachm of Sidon has Attic weight and a Syrian reverse-type. The portrait on one of Tyre is fine. On the earlier tetradrachms of Demetrius II. the king's head is beardless, but on the later, bearded. One of them bears the design which has been supposed to represent the monument of Sardanapalus. Of this Demetrius there are also Ptolemaic tetradrachms of Tyre and Sidon. The portrait of Antiochus VI. on his tetradrachms is very fine. That of Tryphon, upon an extremely rare coin of the same denomination, is remarkable for its strange helmet, having the horn of an ibex projecting in front. The tetradrachms of Antiochus VII. and of Alexander II. have portraits; and those of Cleopatra with Antiochus VIII., bear heads of the queen and king, one behind the other. Seleucus V. is represented by copper coins; there are tetradrachms with portraits of Antiochus VIII. alone, Antiochus IX., Seleucus VI., Antiochus X., Antiochus XI., Philip, Demetrius III., and copper coins of Antiochus XII. The tetradrachms of Tigranes have the bust of the king wearing a strange oriental head dress. The series closes with copper pieces of Antiochus XIII.

In Commagene we may notice the autonomous and imperial cop-

Greek
Coins.

Greek
Coins.

Seleucis
and Pieria,
&c.

per coins of Samosata, and the pieces of Zeugma of the latter class. There is also copper money of the kings of Commagene. In Cyrrhestica there are unimportant autonomous copper coins, and not very numerous imperial pieces in the same metal. Those of Berœa, Cyrrhus, and Hierapolis, of the latter class, may be mentioned. There are a few autonomous copper coins of Chalcidene, but Palmyrene is not represented. Copper pieces are indeed known, purporting to be of the famous Zenobia, struck at Alexandria of Egypt; but those we have examined are doubtful or false. In Seleucis and Pieria the series of the great city of Antioch on the Orontes must be first noticed. There are autonomous copper coins, but those of the imperial class are far more numerous and important. They form a very large series, extending through nearly the whole period of Græco-Roman coinage. The types are not of much interest, and are very few in number; while the art of the coins is generally rude, although some of the silver pieces are in a fair style. The series has, however, a historical value, in showing us what emperors here struck money, and therefore ruled in Syria. The silver coins are of base metal, which becomes potin, and even at last copper washed with silver. In weight they are very low Attic tetradrachms, each being equivalent to four denarii of the early empire. They do not lose weight by degrees, but the quantity of pure metal constantly decreases. They commence under Augustus, and last as late as the time of Volusian. The Era according to which the earlier are dated is the Cæsarian, except during the reign of Augustus, and part of that of Tiberius, when the Actian was used. After Nero the tetradrachms bear no such date, the emperor's tribunitian year taking its place. The obverse bears the head or bust of an emperor or empress, and the reverse, the city seated, or an eagle upon a thunderbolt or club. The eagle, with sometimes a symbol or letter between its legs, becomes at a late period the constant reverse-type. There are copper coins having Greek inscriptions, and others contemporary with them having Latin inscriptions, although after a time the two kinds merge into one, with Greek inscriptions, except that the Roman S. C. in Latin letters is added. It is to be remarked, that on some pieces of the last class the city is called a colonia, having been constituted one by Caracalla. The autonomous copper coins of Apamea may be noticed, as bearing an elephant for a reverse-type. Of Laodicea we must mention late tetradrachms, doubtless of the Roman period, and of the same standard as those of Antioch: their obverse-type is a turreted and veiled female bust, personifying the city. There are also autonomous and imperial copper coins. Seleucia is represented by late autonomous tetradrachms of the same kind as those of Laodicea, and with the same type on the obverse, as well as by copper coins. In Coele Syria there are some copper coins of Damascus, both autonomous and imperial, and others in the same metal of a king Aretas. It is not certain to which, if any, of the sovereigns bearing his name, mentioned in history, this Aretas corresponds. In Trachonitis there are only a few imperial copper coins of Cassarea Panias; and in Decapolis there is a small number of pieces, of the same class and metal, of some of the cities.

Phœnicia.

The money of Phœnicia is more interesting than that of the countries last mentioned. Here the autonomous coinage again becomes important, and affords us some indications of the ancient power and wealth of the great commercial people from whom the region takes its name. The earliest coins, however, are classed with those of Persia, and were no doubt mostly struck under Persian rule; while such as were probably issued independently are sufficiently oriental in character to belong rather to that kind than to the Greek. Of Berytus there are copper coins both autonomous and imperial; those of the latter sort are numerous, and struck by the city as a colonia. Of the imperial copper coins of Byblus, one of Macrinus may be noticed, as bearing for its reverse-type the representation in perspective of a temple of curious construction, one of the many illustrations of architecture which this class affords. The silver pieces of Sidon are tetradrachms and didrachms of the Ptolemaic talent. The obverse bears the bust of the city, personified as a female veiled and turreted; and the reverse the eagle of the Ptolemies. The earlier of the coins are of good work on the obverse, although not of a high style. The

autonomous copper coins have interesting types, among which we may notice Europa carried by the bull; a device mentioned by Lucian as borne on the money of this place. Some of the coins of this class have Phœnician as well as Greek inscriptions. The imperial copper does not form a long series: it first bears Greek inscriptions, but afterwards Latin as a colonia. The coins are dated by two eras, the first supposed to be that of the Seleucidæ, the second that of the autonomy of the town. The autonomous and imperial coins of Tripolis must be mentioned. Next in order stands the series of Tyre. This comprises many silver autonomous coins, the principal pieces being tetradrachms of the Ptolemaic talent. The obverse-type is a laureate and beardless head, seemingly of Hercules; and the reverse-type a Ptolemaic eagle, behind which is a palm-branch. The head may perhaps be assimilated to the portrait of a Ptolemy. None of the pieces are fine, but a few have some merit. There are also autonomous copper coins, as well as imperial pieces of the Roman colonia. The dates are in two eras, as at Sidon, supposed to be that of the Seleucidæ, and that of the autonomy of Tyre. There can be no doubt that some of the early so-called Persian coins must have been struck at Tyre. These may be distinguished by future investigations. The insular city of Aradus is represented by an interesting series. This probably commences with Phœnician pieces issued under the Persian rule, but such have not been positively attributed. The most important Greek coins are tetradrachms, having for their obverse-type the turreted and veiled bust of the city personified, but of Phœnician weight, unlike the similar coins of Syrian cities. They are of poor work, and bear dates in the Era of the Seleucidæ. Drachms, which appear from their style to be somewhat earlier, have on the obverse a bee, and on the reverse a stag, behind which is a palm-tree—types of Ephesus. These must be of the Attic standard, somewhat depreciated, unless they are of a very heavy Phœnician weight. There are copper coins of Phœnicia, having Phœnician letters only, and at least generally subsequent in time to the Persian domination. These require careful study in order to their satisfactory classification to the cities which issued them.

In Galilee there a few imperial copper pieces of Ptolemais, Judæa, &c. Sepphoris, and Tiberias; and in Samaria, some of Cæsarea, and a greater number of Neapolis. In Judæa there are no autonomous coins of Jerusalem, although the pieces supposed to have been issued by Simon the Maccabee were no doubt there struck. There are, indeed, some imperial copper coins of the colonia Ælia Capitolina, founded on the ruins of Jerusalem by Hadrian. It may also be mentioned that there are a few copper pieces, both autonomous and imperial, of Ascalon and Gaza. By far the most interesting coins are, however, those with Hebrew inscriptions, which are usually assigned, and we believe justly, to Simon the Maccabee. These are shekels and half-shekels, respectively equivalent to tetradrachms and didrachms of the Egyptian talent.¹ The shekels bear on the obverse the pot of manna, with the inscription, שֶׁקֶל יִשְׂרָאֵל ("The shekel of Israel"), and the letter ש, for שנה ("year"), followed by a letter indicating the date; and on the reverse, Aaron's rod that budded, with the inscription יִשְׂרָאֵל הַקֹּדֶשׁ ("Jerusalem the Holy"). The half-shekels have the same types, but their reverse inscription is חֲמִישֶׁת הַשֶּׁקֶל ("Half-shekel"). The dates which occur on either shekels or half-shekels are those of the years 1, 2, 3, and 4. The letters are in what is called the coin character, an old form of Hebrew. The weight of the coins shows that they must have been struck under either the Ptolemies or the Seleucidæ; and in the latter case they may be compared to the pieces of Phœnician cities following the standard of the kings of Egypt, although issued under the authority of the Syrian kings. During the period thus indicated we find that the right of coining money with his own stamp was granted to Simon the Maccabee by Antiochus VII.;² and there would be no question that this was the date of these pieces, were it not that it is said that the Jews adopted as an era the previous establishing of the freedom of the country by the treaty of Simon and Demetrius II., between two and four years earlier.³ This difficulty may, however, be explained, if we suppose either that Antiochus merely con-

¹ M. Ch. Lenormant finds fault with Josephus for saying that the shekel is equal to four Attic drachms (*δὲ δὲ σικλὸς νόμισμα Ἑβραίων ὢν, Ἀττικὰς δέχεται δράχμας τέσσαρας*, *Ant. Jud.* iii. 8, 2). He argues, that the weight of the so-called Maccabean shekel being that of a Phœnician tetradrachm is much below that of an Attic tetradrachm (*Revue Numismatique*, Fr., 1845, pp. 180, 181). It is perfectly true that there was this difference between the Maccabean shekel and the contemporary Attic tetradrachm; but Josephus must be understood to speak of the Attic tetradrachm or drachm of his own time. By gradual depreciation the Attic drachm had come to be equivalent, under Augustus, to the Roman denarius, so that the two coins were considered thenceforward identical; and thus pieces struck at Ephesus a little earlier than the time of Josephus which have the weight of a denarius and of two denarii, bear respectively the inscriptions ΔΡΑΧΜΗ and ΔΙΑΔΡΑΧΜΟΝ. At the same period the denarius was almost exactly equal to the quarter of a Maccabean shekel. There is no question, then, that Josephus was right in saying that the shekel was equal to four Attic drachms, meaning the current Attic drachms, and not the older pieces of the full weight. It may be noticed that the later coins of the same kind subsequently mentioned are shekels of the old weight, and their quarters struck on Roman denarii. There is no reason, therefore, to suppose that the Jewish coins show a depreciation like that of those with which Josephus compares them.

Greek
Coins.

firmed privileges before granted by his brother,¹ or else that he gave his sanction to the Jewish money already issued. There are also copper coins of subsequent princes of Judæa, ending under Agrippa II. Their inscriptions are at first in Hebrew and in Greek, but afterwards in the latter language only. Of a later period there are autonomous silver and copper coins, with Hebrew inscriptions, like those of the coins assigned to Simon, but with a difference in the form of the characters. There are shekels of this class, which, notwithstanding their strange fabric, appear to be genuine. The smaller silver coins are usually or always re-struck Roman denarii, and cannot be doubted. The proper name that occurs on both, as well as on the copper, is שִׁמְעוֹן. There is no doubt that these pieces were issued by Barchochebas, who raised the Jews in the time of Hadrian; but it is doubtful whether the name Simeon refers to him or to Simon the Maccabee. There is also a class of uncertain imperial copper coins of Judæa, which may perhaps have been struck at Jerusalem.

Arabia, &c.

Of Roman Arabia there are imperial copper coins of the country generally, as well as of the cities Bostra and Petra. In Mesopotamia the autonomous coinage is unimportant; but the imperial copper money of Carrhæ, Edessa, Nisibis, and Rhessæna is worthy of notice. There are also coins of the kings of Edessa, generally bearing the name of the contemporary Roman emperor or empress; a few are denarii, but the greater number are copper pieces. Of Assyria, there are autonomous copper coins of Atusia ad Caprum, and imperial pieces in the same metal of the famous Nineveh as a Roman colonia, with the name NINIVA OLAVDIOPOLIS. The known coinage of Babylonia is very scanty. It is possible that among the earliest money of what is termed the Persian series there may be some of the last days of the old kingdom of Babylon. There are copper coins of Molon and Timarchus, kings of Babylon, of a much later period. The former was a satrap of Media who rebelled against Antiochus III., B.C. 223, and was defeated and slew himself B.C. 220. His money shows that he took the title of king.

Egypt.

The coins of ancient Africa, including Egypt, are far less numerous than those of the other two continents. The most important series is that of Egypt. There are no coins that can be assigned to the period anterior to the conquest by Cambyzes, nor do the Egyptian monuments bear any representations of money; but we learn from them that gold and silver were kept in rings, and weighed when their value was to be ascertained. From the time of Cambyzes, Persian coins must have been in circulation in Egypt; and indeed Herodotus tells us that Aryandes, governor under this king and Darius Hystaspis, was put to death by the latter for issuing silver money. In the Persian series there are some pieces in a kind of spurious Egyptian style, which are not improbably of Aryandes. The certain coinage of the country commences with that of the first Ptolemy, bearing his name. There can be little doubt that some of the money of Alexander the Great was struck in Egypt; and it seems most probable that Ptolemy issued coins first for Philip Arrhidæus and then for Alexander Ægus, the titular kings in whose names he governed in the earlier part of his rule. The proper Ptolemaic coinage is in the three metals. The gold and silver pieces are adjusted to the Ptolemaic or Alexandrian talent, but there are examples of Attic weight in one reign. The principal denomination of gold money is the octodrachm, but the pentadrachm and tetradrachm are also found. In silver the chief coin is the tetradrachm, but there are also decadrachms. The copper coins are adjusted to an Egyptian talent, distinct from that of the other money, and probably representing the old native system. The gold and silver pieces of the earlier Ptolemies are comparatively numerous, and are chiefly of the heavier denominations. Their art is superior to that of the money of the later princes, of whom there is scarcely anything but copper. The art of the first period is fair, the portraits being usually good in style, and sometimes, in the case of the queens, excellent. The designs, except the portraits, are uninteresting, and of no great variety. The whole series requires a more careful examination than it has yet received in order to its accurate classification. It is especially desirable that the indications of places of mintage offered by the coins should be considered. At present scarcely anything can be said, but that it is probable that many were struck in cities of Cyprus and Phœnicia, although some must have been issued in Egypt, particularly after the loss of foreign dominion. The chief coins of the first Ptolemy are pentadrachms in gold and tetradrachms in silver. In both the king's bust occupies the obverse, and an eagle on a thunderbolt, the reverse. The portrait is good. The tetradrachms, which are very numerous, bear dates. Some of the copper coins of this reign have, on the one side the bust of the king, and on the other that of Berenice. To the time of Ptolemy Philadelphus we must assign gold octodrachms and tetradrachms, with, on the one side,

Greek
Coins.

the portraits of Ptolemy I. and Berenice, and on the other, those of Ptolemy II. and Arsinoë. It is probable that most of the silver coins of the second Ptolemy bear his father's portrait. Of his queen, Arsinoë, there is a fine series of both gold and silver pieces. The gold coins known are principally octodrachms, and the silver are all decadrachms. The obverse-type in both cases is the head of the queen, with a tiara and veil, a good design, but not in the best style; and the reverse-type is a double cornucopiæ. Of Ptolemy Euergetes there are fine gold octodrachms, having on the obverse the king's bust, wearing a radiate diadem and an embroidered chlamys, and with a sceptre-like trident; and on the reverse a radiate cornucopiæ. The portrait is in a good style. Of Berenice there are gold and silver coins, some of which have Attic weight. The portrait is generally of good style, and in one case very beautiful and somewhat different from the common one, though its attribution is confirmed by the fame of this Berenice's beauty. Tetradrachms, in silver, of Ptolemy Philopator are known; and octodrachms, in gold, of Arsinoë. The obverse in both cases is occupied by a portrait, that of the queen being of great beauty. Of Ptolemy Epiphanes there are gold octodrachms and silver tetradrachms, both bearing his portrait, well executed. Tetradrachms of Ptolemy Philometor likewise occur. The coins of the later Ptolemies are not yet satisfactorily classed. They are, as already noticed, principally of copper. There are silver coins, didrachms and drachms, bearing on the obverse the bust of a young man in the character of Bacchus, which are doubtless of Ptolemy Neus Dionysus, or Auletes. The Egyptian coinage of the famous Cleopatra seems to have been only of copper pieces. They bear her bust on the obverse; the face is intelligent, but not beautiful. Her head, with that of Mark Antony, occurs on silver coins of the Roman province Asia. The greatest portion of the Ptolemaic copper money cannot be exactly classed, since it bears no indication of the reigns during which it was issued; so that difference of style is the main guide. The common types are, for the obverse the bearded head of Jupiter Ammon, and for the reverse an eagle on a thunderbolt. Some of these copper coins are very large and heavy.

Of the Roman period, the imperial series of Alexandria, whether we consider its extent or the interest of its types, is the most remarkable in its class, and deserving of far more study than it has received. It commences under Augustus, and terminates with Constantius I. and Galerius Maximianus; thus lasting longer than the Greek imperial money elsewhere. In the earlier part of the period there are potin coins, representing silver money, and most probably meant for tetradrachms of the Ptolemaic standard; but the common metal is copper, at first struck in several sizes, including some that are large. The types are very various; they are Græco-Roman, and even purely Roman (though not technically so), Greek, Græco-Egyptian, and Egyptian. The Egyptian types are very interesting, and form a series standing by itself. The coins of this last kind begin to deserve especial attention under Domitian; and those of Trajan, Hadrian, and Antoninus Pius are numerous and interesting. One of the last emperor, dated in his sixth year, is particularly important, as commemorating the commencement of a Sothic Cycle, A.D. 139:² the type is a crane, the Egyptian ben-nu or phoenix,³ with a kind of radiate nimbus round its head, and the inscription is AION. The coins of the subsequent emperors are less important. About the time of Claudius Gothicus, and thenceforward, there seems to be but one size of coin, the material of which is copper, generally or always washed with silver. The coins of the Nomes of Egypt form a remarkable class. They belong to a short period, the earliest being dated in the eleventh year of Trajan, and the latest in the eighth year of Antoninus Pius. Their metal is copper, and they are of different sizes. There can be no doubt that they were struck at the metropolis of each Nome. The types relate to the local worship, and thus illustrate the Egyptian religion. The inscriptions are the names of the Nomes. There is an exceptional coin of the town of Pelusium. (The work of Zoëga affords the best account of the coinage of Egypt under the Romans.⁴)

Passing beyond Egypt, we may notice that there are a few Libya, &c. autonomous coins of Libya, and, in Marmarica, of Petra. In the Cyrenaica there is an interesting series of Cyrene. The gold coins are numerous, and of the time of good art, some showing a decline. The heaviest pieces are Attic staters or didrachms, bearing on one side a victorious quadriga, in the earlier examples driven by what seems to be a male charioteer, in the later by Victory. Coins of half the weight of these, or gold drachms, have on the obverse a horseman, and on the reverse the sacred silphium plant. On smaller pieces the head of Jupiter Ammon occurs, both bearded and beardless. The weight of the silver coins is at first Attic, but it becomes very light, the tetradrachms being reduced to very nearly an equality with tridrachms, and thus considerably below the Ptolemaic tetradrachms.

¹ Comp. Macc. xv. 5.² *Horæ Ag.*, p. 32.³ *Id.*, p. 40, *et seq.*⁴ *Numi Egyptii Imperatorii* (Gr. Zoëga), 4to, Rom. 1787.

Roman
Coins.

The cause of the change may have been the influence of Rhodian and other light coins, but the occasion is not known; in time it was probably anterior to the rule of Magas. There are didrachms, besides the tetradrachms. The art of the silver coins is sometimes fair, although never very fine. The usual types are, for the obverse the bearded or beardless head of Ammon, the former sometimes crowned with silphium, and for the reverse the silphium plant. Some of the copper pieces are relatively of a fair style. Of the Cyrenaica generally there are Greek and Roman coins, the latter issued by Roman officials. Of the town of Barce there are both gold and silver pieces, the former not being common. The silver series commences with somewhat archaic coins. The standard is Attic, with the same change as at Cyrene. The types are, for the obverse the silphium, and for the reverse the head of Ammon; designs which in some of the later coins change places. In Syrtica the autonomous Roman coins of the colonia Leptis Magna, and in Zeugitana the money of Carthage, are deserving of notice. In speaking of the Siculo-Punic coinage, we have already had occasion to treat of the money of the Carthaginians issued in Sicily. Their African coinage has the same chief types, the head of Proserpine, and the horse or horse's head and palm-tree. It follows the Phœnician talent, and the dodecadrachm and decadrachm are known, besides tetradrachms and smaller pieces. Some copper coins are known of the city of the Roman period with Latin inscriptions. There are a few imperial pieces of towns of Mauritania, as well as an interesting series of the kings of Numidia and Mauritania. There are silver coins of Bocchus, silver and copper of Juba I. and Juba II., as well as the latter with Cleopatra; copper of Cleopatra alone; and silver and copper of Ptolemy. The silver pieces of this series are probably for the most part low denarii. On the whole, the coinage of Africa beyond Egypt is poor and of small interest.

SECT. IV.—ROMAN COINS.

Classes.

The ancient Roman coinage appears to have commenced late in the fourth, or early in the third century B.C., and to have continued without interruption until the fall of the Western Empire, A.D. 476. It will be necessary here to give a sketch of the characteristics of its great classes. The earliest Roman coins are of gold, silver, and copper, of Greek fabric and with Greek types, but Latin inscriptions. Their art shows that they date from about the time of Pyrrhus to near the close of the third century B.C. There can be no doubt that they were issued by Campanian cities subject to the commonwealth. After a time the Romans had a proper coinage of Roman or Etruscan fabric, and with Roman types as well as Latin inscriptions. With this class the proper Roman coinage commences. The period of these coins is different with those of each metal. The silver and copper money probably began about the same time, near the close of the third century B.C.; and terminated, in the case of the former about B.C. 80, in that of the latter somewhat earlier. The late silver coins are of Campania only; and the same is the case with all the gold pieces, which were most probably struck between B.C. 90 and 80. It will be seen that the later coins of this class considerably overlap in time the earlier of the next class, but their types forbid our altering the arrangement. The copper coins, commonly called *æs grave*, are the most important. They are of heavy weight and coarse fabric, bearing rude types, the most common of which are, for the obverse the head of Janus bifrons, and for the reverse the prow of a galley. The silver coins usually have as their obverse-type the head of Minerva, and the gold ones, that of Janus. This class was succeeded, though in an irregular manner, by what is called the family or consular series, the latter of which appellations is incorrect. Its coins are of the three metals, and with Roman types and Latin inscriptions. They were struck at Rome from B.C. *cir.* 170 to the time of Augustus, by individuals to whom the state allowed the right of coinage, whose names they bear, and they are therefore classed according to the Roman families. The gold and silver family coins usually have on the obverse the head of a divinity, or of a personification, or of a traditional or historical personage; and, on the reverse a mythological, symbolical, traditional, or historical subject. They are generally of better art than the *æs grave*, which the copper coins, on the contrary, follow in art as well as in types. The imperial coinage may be considered to commence with that of Julius Cæsar, although the family series does not then terminate. It is of two classes; that of the pagan emperors, and that of the Christian emperors. The former class ends under the reign of Constantine, when he

Roman
Coins.

changed the coinage. The coins are of gold, silver, and copper; the last including brass. Their designs from the time of Augustus to the decline of the empire show a fair style of art, and display great mechanical skill. They most nearly resemble modern coins, particularly in form and thickness, but their designs are generally in higher relief. The obverses bear the portrait of an emperor or empress, or of a Cæsar; and the reverses, historical, mythological, or symbolical types. Towards the latter part of its period the coins become thinner in form and of much lower art and execution. The second class of imperial money, that issued by Constantine for the greater part of his reign, and by his successors to the fall of the Western Empire, is of gold, silver, and copper, and is mainly to be distinguished from the preceding one by the absence of pagan types, and by a further decline in its art. It is important to distinguish the five great divisions of Roman money which we have described, and which may be called the Greek coinage of the commonwealth, the early Roman coinage, the family coinage, that of the pagan, and that of the Christian emperors.

In seeking the motives which influenced the choice of the Devices types of the proper Roman coinage, we must not imagine too and in-close an analogy with the case of Greek money. The idea of scriptio, the first coinage, that of the Campanian cities, which was not properly Roman, was to adopt subjects connected with religion. This feeling was maintained, though it seems somewhat ignorantly, in the *æs grave*. Under the empire, however, the sovereign became the source of the chief types, although the religious motive was, perhaps for a reason of policy, never wholly abandoned. An inscription of the time of Diocletian, *SACRA MONETA AVGG NN (Augustorum nostrorum)*, well expresses this idea; the coinage personified by the goddess is still sacred, but yet it is the emperors'. The proper Roman coinage, if separated according to its types, falls into four classes, the *æs grave*, the family silver and gold (for the copper maintained the old types), the pagan imperial, and the Christian imperial. The designs of the first are, like those of the early Greek coins, sacred distinctive symbols, though, as already noticed, probably not always understood by those who used them. The types of the family silver and gold coins are somewhat different from those of any class of money which we have already noticed. The primary religious motive is indeed to be clearly traced in them; but their having been selected to distinguish families, instead of towns or tribes, gives them a peculiar character. The following are the principal classes to which these types may be reduced:—

1. Head or figure of a divinity worshipped at Rome; as head of Jupiter (*fam. Petillia*), figures of the Dioscuri (*Junia*), or of a divinity worshipped by the family or individual striking the coin, as head of Neptune (*Pompeia*, coin of *Sextus Pompeius*).
2. Sacred natural or artificial object; as pontifical implements (*Antonia*).—This class is not a very large one, and sacred animals rarely occur.
3. Head or figure of a personification of a country or town; as heads of Hispania (*Carisia*), Roma (*Julia*), Alexandria *Ægypti* (*Æmilia*).
4. Head or figure of an allegorical personage; as heads of *Favor* (*Hostilia*), *Pallor* (*id.*), *Honos* and *Virtus* (*Fufia*, *Mucia*).
5. Fabulous monster; as *Scylla* (*Pompeia*).
6. Head or figure of an ancestral personage; as heads of *Numa* (*Calpurnia*), *Ancus Marcius* (*Marcia*).
7. Events connected with ancestors; as figure of *Marcus Lepidus*, as *TVTOR REG [is]*, crowning *Ptolemy Epiphanes* (*Æmilia*).
8. Places connected with historical exploits, and of a votive character; as *Pharos of Messana* (*Pompeia*, of *Sextus*, probably commemorating the sea-fight off *Messana*, B.C. 38).
9. Symbolical representations commemorating contemporary events, as a general welcomed on landing by a country or city (*Minatia*).
10. Heads of living personages exercising dictatorial power, or in very high authority; as head of *Sylla* (*Cornelia*).
11. Representations connected with military matters; as legionary standards (*Antonia*).

Besides the principal designs, there are symbols and numerals, generally to be regarded as having been indicative of successive issues from the mint. The inscriptions are usually, on the obverse the name of the personage represented, with, in the field, \times for denarius, and the like; and on the reverse the name of the person who issued the coin: the latter sometimes occurs on the obverse. The inscriptions are in the nominative,

Roman
Coins.

The series of Roman imperial coins of the pagan emperors (commencing with Julius Cæsar, and terminating with the adoption of Christian types by Constantine the Great) bears devices of the same general character as those of the family money, but with a far stronger relation to living persons and events than to mythology. The obverse-type of this period is the portrait of an imperial personage, an emperor, an empress, or a Cæsar; and the reverse bears some subject directly or tropically connected with their actions. Under Julius and Augustus moneyers of powerful families shared the right of issuing coins with the head of the state; their money is like that of the family series, to which it should be assigned, but it generally bears on the obverse the head of the emperor, if we may include Julius with Augustus under that name. In the reign of Augustus, however, this privilege ceased; and the emperor struck the gold and silver money, while the copper was issued by the senate, and therefore always bears the characters S. C., for *Senatus consultu*. Without repeating what we have said of the types of the Roman family coins, we may mention the principal kinds of types of the imperial coins. Those of the obverses vary only in the treatment of the head or bust of the imperial personage. Those of the reverses are commonly mythological, representing divinities; or allegorical, representing personifications; or historical, representing, either directly or tropically, acts done or works executed by the reigning emperor. Thus the coins of Hadrian, besides bearing the figures of the principal Roman divinities and personifications, commemorate, by allegorical representations of countries or cities, the emperor's progresses, and, by actual representations, his architectural works. The inscriptions of the coins of the pagan empire are either simply descriptive, such as the emperor's names and titles in the nominative, on the obverse, or partly on the obverse and partly on the reverse, and the name of the subject on the reverse; or else they are dedicatory, the imperial names and titles being given on the obverse in the dative, and the name of the type on the reverse. On the latter there is sometimes a directly dedicatory inscription to the emperor. The inscriptions of the earlier imperial coins, from Tiberius to Alexander Severus, have generally a chronological character, usually giving the current consulship of the emperor, or his last consulship, if he did not at the time hold that office, as well as the year of his tribunitian power. In the latter part of the third century an indication of the towns at which the coins were struck commences, usually occupying the exergue of their reverses. There are also sometimes characters or signs in the field. The geographical indications are not completely understood, but it is probable that they generally mark not only the place of striking, but each fresh issue of the same type.

The coins of the Christian empire differ from those of the pagan empire mainly in the character of their reverse-types. These are generally allegorical and free from pagan intention, though not from pagan influence, as in the cases of the common types of Victory inscribing the emperor's *vota* upon a shield, or in later times holding a long cross, and of seated Rome. Purely Christian types are less common: the most remarkable is that of the monogram of the name of our Saviour, formed of X and P, the latter letter being placed vertically across the former. The inscription HOC SIGNO VICTOR ERIS, on coins dating not many years after the victory of Constantine over Licinius, must also be noticed. The inscriptions generally show the same change as the types. There are many varieties, but very few absolutely different types and inscriptions.

Art.

Roman coins, if classed according to their art, fall into three main divisions,—that of rude and slightly progressive art, that of the best art, and that of declining art. The period of the first class commences with the issue of the *æ*s grave, about the latter part of the third century B.C., and lasts to the accession of Augustus; that of the second comprises the reigns of that emperor and his successors, as far as the death of Commodus; and that of the third extends from this time to the close of the empire. The case is a very different one from that of the Greek coinage, for the improvement of art in the time before Augustus is in general very slow, and the great advance made in his money is owing to a better system, and the employment of Greek artists. The decline, which sensibly commences in the reign of Commodus, although his coins are generally of good style, is not very rapid, and receives occasional checks, until, at the time of Diocletian, there is a sensible improve-

ment, which, however, is more evident in the execution of the coins than in their designs. The money of Constantine the Great is perhaps the best of this time; under his sons decline has again begun, and it steadily, though still slowly, continues until the close of the empire.

Roman
Coins.

We shall here speak only of the best art of Roman coins, as in the case of the art of Greek coins, and for stronger reasons. The art of Roman coins is not steadily progressive from internal vigour, and in its time of excellence is far more foreign than native in character. It is, however, well worthy of study, in this period, for its intrinsic merit, for its illustration of contemporary sculpture, and on account of its influence on mediæval and modern numismatic art. The Roman coins were designed under the revival of Greek art, during the empire, by the Græco-Roman school. The Romans had properly no art of their own. Their greatest temples, and the statues of their gods, were essentially copies or imitations by Greeks of Greek works, except, in the case of the statues, some few Greek originals of an earlier time. Both differed from the best Greek works in a want of simplicity and purity of design and execution, and the statues show a tendency to pictorial and dramatic rather than ideal treatment. The portrait statues and busts are most characteristic of this style. With an evident faithfulness, they usually show a deficiency of grandeur, and occasionally some mannerism. Perhaps the most excellent example of this class is the bust commonly called that of Clytie, in the British Museum, which is undoubtedly a portrait of the Græco-Roman school. The best Roman coins approach most nearly to the excellence of this very beautiful sculpture. As simple medallion portraits, they are indeed scarcely surpassed, except by the still more pictorial Italian medals of the fifteenth and sixteenth centuries; but they never rise to the simple grandeur of the few good Greek portraits that occur on coins. The difference is this: the Greek sculptor seized the highest expression of the face he would represent, and produced an ideal portrait; while the Græco-Roman copied the usual expression, and produced nothing beyond a faithful portrait. The finest examples of Græco-Roman art on coins are the portrait of Livia as Pietas, Justitia, and Salus, and that of the elder Agrippina, on copper coins; and those of the elder and younger Faustinas, in the gold series. The medallions and copper coins of Trajan, Hadrian, Antoninus Pius, and Commodus, are on both sides of excellent design and beautiful workmanship. For portraits, none of the period are more interesting than the coins of Nero, the growth of whose bad passions may be traced in the increasing brutality of his features and their expression. In the case of other emperors, the portraits are either always the same, or taken at two ages. The whole series from Augustus to Commodus is well worthy careful examination, especially as affording some of the best specimens of the work of an important school of ancient art. This Græco-Roman school is seen to far more advantage in these works than in its attempts—and these but imitative—at high sculpture, in which, through an inadequate ideal, it failed to produce anything pure, elevated, and simple. Let any one who would see how far it fell short compare the Venus of the Capitol with the Venus of Melos.

We have already had occasion to speak of the mode in which Systems of Roman coins were struck, and we may now pass on to consider coinage, the denominations of the coinage at different times. The subject is one of extreme difficulty, from the disagreement of the evidence of ancient writers with that of the coins themselves, and the obscurity of the indications offered by the latter. It was believed, until lately, that some existing Roman coins were as early as the period of the kings, from the statement of Pliny, that Servius Tullius first struck copper money, and from the ancient appearance of the specimens in question. Any such theory is, however, wholly untenable. The earliest Roman coins, as we have already mentioned, were of Greek fabric, and issued by Campanian cities. The gold and silver appear to follow the Greek system of the Attic talent, while the copper are on the Italian system. The denominations of the second class are, in gold, the aureus and half-aureus; in silver, the denarius, and its half, the quinarius; and in copper, the *as*, with certain of its divisions. The denominations of the third class, or family series, are in general the same as those of the preceding class, with, in the copper, a depreciation of weight. The denominations of the fourth class—that of the pagan empire—are the same, though again of constantly decreasing weight. The fifth class, comprising the money of the Chris-

Roman Coins.

Gold coins.

tian emperors from Constantine's change in the coinage until the fall of the Empire of the West, has a different system of denominations.

We may now notice the money of each metal in particular, from the commencement of a Roman system with what we have called the second class of Roman coins. Pliny states that the first aurei were struck, forty-five from the pound of gold, B.C. 207; a date which well agrees with what must be that of the oldest silver coins of this class. The gold coins of the same class seem to have been on this standard, for they weigh a little more than a hundred grains, which would indicate that about forty-five were struck from the pound. There is also in this series a half-aureus (a coin of which we do not know the ancient appellation) of this series. The aurei of the next class—the family series—fluctuate in weight. The earliest are somewhat heavier than those of the preceding class; those of the time of Sylla are very much heavier, having been struck thirty to the pound; while those of Pompey are forty to the pound, a reduction mentioned by Pliny. There are no half-aurei of the family series known, but they are found of the reign of Augustus. From the time of Augustus the weight of the aureus was gradually lowered, until Nero fixed the number to be struck from the pound of gold at forty-five, making a corresponding change in the silver money. Caracalla, in A.D. 215, further reduced the aureus by striking fifty from the pound; and many of his successors issued gold coins that were much lighter than the weight thus fixed. Under Constantine the Great a new coin was substituted for the aureus, called *solidus*, or *solidum*, of which seventy-two were coined from the pound. This continued to be the principal Roman gold coin, and to maintain its full weight, to the fall of the Empire of the West, and, indeed, with little change of weight, though latterly much alloyed, until the end of the Byzantine Empire. The divisions of the solidus were the half and third, commonly, but without authority, and, in the case of the latter, incorrectly, called the *semissis* and *tremissis*.

Silver coins.

The principal silver coin of the commonwealth was the denarius, of which there were twenty-five to the aureus. Pliny makes the first denarii to have been struck as early as B.C. 269; but there are no specimens that we can ascribe to an earlier period than the date he assigns to the first aureus—B.C. 207. It may be remarked, however, that since the denarius is derived from the Attic drachm, the Campanian Attic drachms of Greek types might have been considered by Pliny as the first denarii; although the principal gold coins of the same class could not be called the first aurei. In this case the date would perfectly apply. The denarius received its name from its being at first equivalent to ten asses. It had two divisions in silver—its half, the *quinarus*; and its quarter, the *sestertius*: the *quinarus*, when bearing the figure of Victory on its reverse, was termed *victoriatus*. Smaller silver coins are mentioned by ancient writers as current under the commonwealth, but no examples of them have been recognised. There are *quinarii* of the second class of Roman coins, that to which the earliest denarii belong. The *victoriati* are said to have been struck by a Clodian law (Plin. *N.H.*, lib. xxxiii., § 13), but it has not been ascertained when this law was enacted. The *sestertii* are all, as far as we know, of a later time. It is said that at first a hundred denarii were struck from the pound of silver; and accordingly we find that the oldest weigh from 50 grains to above 60. In the time of Augustus, however, eighty-four denarii were struck from the pound. When Nero lowered the weight of the aureus, he proportionately reduced the denarius, coining ninety-six from the pound. In subsequent reigns the proportion of alloy was constantly increased, until, in the time of Severus, it was one-half of the weight of the coin. Caracalla, in A.D. 215, legalized a considerable proportion of alloy in the denarius, and issued a new coin, called after him the *Argentus Antoninianus*, of which sixty were struck from the pound—a coin which not very long afterwards supplanted the denarius. The *argenteus* was considerably alloyed, and later emperors made it baser by degrees, until at length it was a copper coin washed with silver, and even tin. The types of obverse introduced by Caracalla were always maintained; they represent the bust of the emperor with a radiate crown, as Phœbus, and that of the empress resting on a crescent, as Diana. Diocletian again issued coins of good silver of two denominations, one of which appears to represent the *argenteus*, though without its types, and the other the denarius. Constantine the Great added other denominations, all which have not been satisfactorily identified among his coins. The principal silver coin of his time was the *centenionalis*, weighing a little less than 50 grains, which was probably first issued by Diocletian. This system was followed to the end of the Empire of the West, although but two denominations were usually struck, which seem to be the *centenionalis* and a piece of half its value.

Roman Coins.

Copper coins.

The earliest proper Roman copper coinage has been generally supposed to be as ancient as the time of the kings. The principles of just criticism forbid us, however, from carrying any of these coins to a remoter period than the latest part of the third century before the Christian Era. The *as*, which was the principal copper coin, is said to have been first coined of the weight of a pound; and therefore when the weight of the denomination had been lowered by authority, these oldest asses were called *librales*. For the same reason, the whole class of heavy copper coins received the name of *as grave* when there was a lighter currency. It is not clear whether this appellation anciently included all the copper money of this kind, whether of Rome or of Etruscan cities, heavier than that bearing the names of Roman families; but this was probably the case. The *as*, like the *libra*, contained twelve *uncia*, or ounces; and the divisions which were commonly struck were the *semis* or *semissis*, its half; the *triens*, or third; the *quadrans*, or quarter; the *sextans*, or sixth; and the *uncia*, or twelfth. The other divisions of the *as* which have been noticed are, according to M. Cohen, the *quincunx*, or five ounces, without Rome; and the *bes* or *bessis*, or eight ounces; and *dodrans*, or nine ounces; which last two have been alone found among the coins of the family Cassia.¹ The Roman pound has been estimated by Böckh at 5053 grains,² but no *as* has been found, as far as we know, nearly equal to this estimate. There are, however, specimens which are of not much less weight; and if we make allowance for waste by rusting and for irregularity of striking, which is especially great in almost all copper coinage, and generally below the standard, we may consider they fairly represent the *asses librales*. An examination of the divisions of the *as* leads to the same result. There are also larger pieces of metal of greater weight than the *as*, and of an oblong form, bearing on one side the figure of a bull, of which some true specimens remain, although most of those which are in cabinets are forgeries. They are of the period of the *as grave*, and might be supposed to represent the sum of three asses (called *trestiti*), or ten asses (called *decussis*), according to when they were struck; but it is doubtful if they are more than pieces of metal containing a number of pounds without fractions, like the so-called Celtic ring-money. While the earliest asses and their divisions are of nearly full weight, we find the later ones are much lighter. During the period of what we have called the second class of Roman coins, which commences with the issue of a proper Roman coinage, the *as* appears, from existing specimens, to have gradually fallen to the sixth part of its original weight by a degradation that was probably on the whole regular. During the next period—that of the family coins—the asses seem to be only of the weight of either two ounces or a single ounce. Under Julius Cæsar the *as* weighs not quite half an ounce; and we first observe two new copper coins—the *sestertius*, and its half, the *dupondius*. At this time the number of asses to the denarius had already been increased to sixteen; so that the *sestertius*, which was the quarter of the denarius, contained four asses. The *sestertius*, however, and the *dupondius*, were struck of fine yellow brass (*orichalcum*), while the *as* was of copper. Instead, therefore, of weighing two ounces and one ounce respectively, they weighed one ounce and half an ounce; while the *as* weighed nearly half an ounce. The reason that the *as* is defective, rather than the *dupondius* excessive, probably is, that its weight was that to which the coin had already fallen, and that it was considered better to make the new piece of an exact weight than slightly to raise the old one. The *dupondius* and *as*, being nearly of the same weight, and having the same types, are in general only to be distinguished by the difference of metal, and sometimes the more careful work of the former. The rust produced by the chemical action of different soils often hides the colour of the metal, and so takes away the principal means of discrimination; yet the two may usually be distinguished, at least as late as the time of the Antonines, particularly if one is careful to compare them with the *sestertii*, to which the *dupondii* always have a nearer resemblance than have the asses. Divisions of the *as* are very uncommon under the empire. Those which exist are of the period extending from the accession of Augustus to that of Gallienus. From that time it is doubtful if any were coined. The very small pieces issued considerably later do not seem to have corresponded to any one of the old coins. The copper coinage, like the silver and gold, suffered considerable changes. Alexander Severus, or, as he is called on the coins, Severus Alexander, reduced the *sestertius* and *dupondius* to two-thirds of their former weight. A few years afterwards a larger coin or denarius of brass, equal to four *sestertii*, was issued, called the *Philippus æreus*, from the Emperor Philip, who seems to have first struck it. In the time of Gallienus the *sestertii* and *dupondii* cease altogether, at least as a regular series, and the principal coin seems to

¹ *Monnaies de la Rép. Rom.*, p. vii.

² *Metr. Untersuch.*, p. 165.

Roman
Coins.

be the *as*, now a small piece coined of brass, and some larger pieces, generally *Philippi aerei*. In the reign of Diocletian a new coin of copper, frequently plated (the *foliis* or *terurtianus*), was introduced; and the *Philippus aereus* appears to have been abandoned at the same time. The smaller coin, which is also of copper, appears to be the *assarion*. Constantine the Great changed the copper coinage; but he seems to have taken the money of Diocletian as the basis of his coinage. His copper money consists of two principal denominations, which differ only from those of Diocletian in being somewhat lighter, and the half of the smaller coin. Thenceforward, to the end of the empire, there was no very important change, except that the largest coin, the *foliis*, fell into disuse after the time of Honorius, and that there was a constant diminution in the weight of the others. The common division of the Roman copper money, according to its size, is into first brass, second or middle brass, and third brass. The first class includes the *sestertii*, the second the *dupondii* and earlier *asses*, the third the later *asses* and all smaller coins. It is not necessary to show the faults of an arrangement that is so thoroughly unscientific in character; but we must protest against its use in the arrangement of cabinets, and the consequent injury to the real progress of numismatic inquiry.

Medallions
and tickets.

In addition to the Roman coins, there are certain pieces which cannot be properly considered to have been money. These may be classed as medallions and tickets. The medallions are of gold, silver, and brass or copper, and usually larger than the largest coin of the time of their metal. They are generally, if not always, of the weight of a number of coins without fraction; but they are not therefore to be considered as part of the currency. The gold medallions commence under Constantine the Great, and continue to the end of the empire; the silver probably commence under Gallienus, and last to the same time; and the copper commence with Augustus, and continue at least to the reign of Alexander Severus. The types resemble those of the coins, but have an especial reference, in the case of the copper pieces, on account of their having been set in the standards, to military matters. The work of all is usually finer than that of the current money. Of the tickets, the most interesting are the *contorniates*, which were probably struck between the time of Constantine the Great and the fall of the empire, and were connected with the games.

(The most valuable treatise on the entire class of Roman coins is the part of Eckhel's *Doctrina Numorum Veterum* which relates to it. Except with reference to the family series, no great advance has been made since its publication; and on the whole it is both the most complete and the most learned account of Roman money. Mionnet's work, entitled *Médailles Romaines*,¹ is of far less importance. It has the two cardinal defects of not describing the most common types, and of following no scientific arrangement. There are several excellent essays on particular branches of the subject, which we shall have occasion to notice in subsequent places.)

Chief
classes of
Roman
coins.

Without considering in detail every kind of Roman money, it will be necessary to make some observations on the chief classes, the early proper coinage of the city, the family series, and that of the empire. Of the first kind, the *as* grave is beyond doubt the most important portion. It must not be supposed, however, that it is all of Rome; for it is certain that much was issued by other cities, although there is a great quantity that we must believe to be properly Roman. The *as* of Rome is known by having on the obverse the head of Janus bifrons, and on the reverse the prow of a galley, to which Ovid alludes, asking—

“Cur navalis in aere
Altera signata est, altera forma biceps?”

(*Fast. i.*) Other denominations have different obverses, with the same reverse, and must have been struck at Rome or under Roman authority. Coins of other types are to be generally referred to cities in the neighbouring provinces. (The most complete work on the *as* grave is that by M.M. Marchi and Tessieri, already noticed.)

Family
series.

The series of family coins consists mainly of *denarii*, other pieces, both in gold and silver, being comparatively rare, and even the copper money of the same class being not so numerous, and showing far fewer varieties. The types of the *denarii* are of high interest, especially when they relate to the Roman traditions, or to earlier or contemporary history. Those that refer to the story of Romulus, or bear the heads of others of the primæval kings, or commemorate events assigned to this first age of the city, show how strong a hold the early Roman legends had taken upon the mind of the people in the first and second centuries before the Christian era, at times mainly anterior to similar written evidence. These types are for the most part not the common devices of the nation, but proper to each family; and they thus indicate the general feeling more clearly than those of Greek cities, which gave

no scope to individual choice. The family coins that record the achievements of the house, whether in days past or in the time when they were issued, are also of high interest. The memory of events not yet recognised in written history is thus preserved, and in such a manner as to lead us to hope that we may, with the aid afforded by the coins, restore otherwise lost portions of the annals of the city. It is important to observe,—there can be no doubt, owing to historical considerations, differences of style, and evidently local types,—that many family coins were struck not alone out of the city, but in provinces beyond Italy. We may notice a few of the types of *denarii*, taking the families in an alphabetical order. Of the family *Æmilia* there are interesting coins relating to deeds performed or structures raised by members of that house. One bears the head of Alexandria on the obverse, and on the reverse Marcus Lepidus crowning Ptolemy Epiphanes. Another has a representation of Paulus *Æmilius* as if raising a trophy, with Perseus, king of Macedon, and his two children, standing before him. The coins of Mark Antony, which belong to the family *Antonia*, display his power and arrogance. To Junia is assigned the money of the celebrated Brutus. The most remarkable coins in the family series, were they undoubted, would be those of Brutus commemorating the death of Julius Cæsar, with on the reverse a cap of liberty between two daggers, and the inscription *EID. MAR.* There are specimens in both gold and silver, the latter having two types of obverse; but we have seen none that could be pronounced satisfactory. Dio Cassius indeed says that such a commemorative type was placed on his coins by Brutus; but it is not unlikely that all the pieces bearing it would have been called in by the triumvirs, while the passage would have stimulated modern forgers to produce what it describes. Among the types of the coins of the family *Marcia* we notice the head of King Ancus Marcius. The coins of the family *Pompeia* are of great interest. The most remarkable one has on the obverse the Pharos of Messana above a Roman galley, and on the reverse Scylla striking with a rudder; types supposed to relate to the defeat of the fleet of Octavianus, B.C. 38, near Messana, by that of Sextus Pompey; or possibly referring to the earlier battle in the straits of Sicily, B.C. 42, between the same, and with the same result. The coins of the family *Tituria* present two noticeable types, one representing the Romans carrying off two Sabine women, and thus commemorating the Rape of the Sabines, and the other, Tarpeia being crushed by bucklers. (The best work on the family coins is that of M. Cohen.²)

Roman
Coins.

The imperial series is properly the continuation of the family Coins of class, although characterized by marked distinctions. The deno- the empire. minations present a more perfect system, as we might have expected; and the reference of the types is either to the state or to the emperor. The types of the later family coins, however, from the time of Sylla, when the liberties of Rome were already overthrown, are very frequently similar in intention to those of the imperial money. The whole class may be separated into three main divisions, the first comprising the coins of the period extending from the rule of Julius Cæsar to the death of Commodus; the second, those of the subsequent time, as far as the accession of Constantine; and the third, those of that sovereign and his successors to the fall of the Empire of the West. The coins of the first period have that general character of order and fitness that we should expect in the money of a great empire, and at the same time show such changes as would be made by a nation which despised commerce, and was strong enough to carry its contempt into acts. Under the outward system of regularity there lay an element of disorder that brought about in the end financial ruin. The principles that worked little harm in an age of prosperity were engines of destruction when the state was overtaken by adversity. No longer sustained by a powerful government, or applied with moderation, slight changes took the form of desperate experiments, each one of which left the exchequer in a position of greater difficulty. In the period we are now noticing, we find but the commencement of this disorder in the constant though small decline of the weight of gold and silver coins, and the legalization of their moderate reduction, a system which did but continue the custom of the commonwealth, under which there had been far greater changes. The chief coins are the aureus, the denarius, the sester- tius, the dupondius, and the *as*. Denominations lower than these are not common. There is a general similarity of types, especially in the case of the aurei and *denarii*. On the whole, the best work is shown in the *sestertii*; but the *dupondii* are often excellent, as well as the aurei and *denarii*. The types have for the most part a reference to the emperor rather than to the state, although this is less marked at the first than afterwards. The coins of Augustus show a decided advance in their art upon those of Julius; but in this respect they must yield to those of Livia, Antonia, and Agrip-

Roman
Coins.

Coins of the
empire.

pina the Elder, which are among the most excellent Roman coins. The portraits of Livia, as Salus, Justitia, and Pietas, on dupondii, are among the most beautiful examples of Græco-Roman art. The bust of Antonia on aurei and denarii, as Ceres or Proserpine, is a finer subject, scarcely less ably treated.¹ The portrait of the elder Agrippina on sestertii is quite equal to those of Livia in work, although the face is not so beautiful. The coins of Drusus Senior bear types relating to his conquest of the Germans. The denarius of Tiberius is interesting on account of the description of it in the New Testament with reference to the question of the lawfulness of paying tribute. The sestertii of Nero are of very fine work, and in this respect yield to no other coins in the series. The money of Vespasian and Titus records the subjugation of Judæa. The coins of Trajan are remarkable for their architectural types; and those of Hadrian as commemorating his journeys. The portrait of Antoninus Pius is fine; and that of the elder Faustina is among the most beautiful. The head of Marcus Aurelius is also well executed; and that of the younger Faustina is always beautiful, and sometimes inferior to none in the series, when the empress is represented as very young, probably in the character of Venus, whose name and figure occupy the reverse. The imperial ladies are distinguished by the manner in which they wear their hair, which is sometimes a safer guide than the portrait. The coins of Commodus may be considered to close the series of those showing good art: some of them display great delicacy and careful work. Among the more interesting pieces is the copper medallion, having on the reverse Roman Britannia seated.

The disorders that followed the death of Commodus have left their impress on the coinage, which then lost its beauty of design and delicacy of execution, neither to be more than partially restored in after times. The money of Severus and his house, which shows systematic lowering of value, is of interest. The base metal *argenteus* is already found in the time of Niger, but it was not regularly introduced until the reign of Caracalla. The coins of Elagabalus are remarkable for their reference to the oriental worship to which he was attached. Under Alexander Severus, the copper money was legally reduced, and great attention was paid to its execution, which is excellent for the period. The art and purity of the money declined after Alexander's reign, and in that of Gallienus both had sunk to a very low condition. The chief coins of this emperor, and the so-called "Thirty Tyrants," were the *argentei*, which were of copper or base metal washed with silver, and brass pieces of the same size, commonly called "third brass," which are first plentiful at this time. With the accession of Aurelian the Greek imperial money may be considered to cease, except at Alexandria; and thenceforward very much of the Roman coinage was struck in the provinces. After a time we notice the abbreviated names of the towns of mintage in the exergues of the coins; a practice which appears to have commenced in the reign of Gallienus, but not to have attained a regular form until that of Diocletian and Maximian. About the period of the latter, Treves, Lugdunum (*Lyons*), Arles, Londinium, Rome, Constantinople, Antioch, Alexandria, and Carthage, and afterwards Ravenna and Milan, are the most common mints. The changes of Diocletian, although they improved the material of the coins by substituting pure silver pieces for the base *argentei*, and added the large copper follis to the third brass, did not materially affect the types. Throughout this period they are of inferior interest to those of the prosperous age that preceded it. Their reference is rather to divinities than to events, and they show a want of originality. With Diocletian, however, the art of the coins improves, a stiff style being introduced, which, notwithstanding its radical faults, is not devoid of force. In the treatment of heads it is more happy than in that of groups.

The commencement of the third period of Roman coinage we have dated in the reign of Constantine the Great. The proper beginning cannot be exactly fixed; for it would be difficult to choose between the monetary changes of this emperor and his abandonment of pagan designs and adoption of others, either connected with Christianity or supposed to be not repugnant to it. The two events do not, however, seem to have been far apart. The recognition of Christianity was not the cause of such great immediate changes in the types as one might have supposed. A little earlier several types of a symbolical or allegorical character had been introduced, and these were retained. The Christian types at first are very few, and they can scarcely be said to pre-

dominate during any part of the remaining period of the Western Empire. The art of Constantine's money resembles that of Diocletian's; but after his time there is a speedy decline, and towards the close of the empire the coins are in this respect very poor. The most interesting coins are the third brass pieces of Constantine, with the Christian monogram upon the standard (*labarum*), and the somewhat later folles, as those of Vetricano, with the inscription *HOC SIGNO VICTOR ERIS*. The coins of Julian the Apostate are to be noticed on account of their showing a recurrence to purely pagan designs. On the whole, it may be considered that the change of religion was fatal to the types of the coins, no doubt because it took place at a time when the art of the empire was in too low a condition to be capable of expressing new ideas.

SECT. V.—MEDIÆVAL AND MODERN COINS OF EUROPE.

The period of the mediæval and modern coins of Europe must be considered to commence about the time of the fall of the Western Empire, so that its length to the present day is nearly 1400 years. The many groups into which this great class is divided are so remarkably different from one another that it cannot be treated, like the Greek or the Roman series, as a whole. It is also impossible to separate the mediæval and modern coins, either in the entire class, because the time of change varies, or in every group, since there are usually pieces indicative of transition which display characteristics of both periods. The clearest division is, to place the Byzantine coinage first alone, and to consider the rest of the class as possessing a kind of general similarity, though of the widest sort.

The Byzantine money is usually held to begin in the reign of Anastasius, A.D. 491–518. The coinage is always in the empire, three metals, but the silver money is rare, and was probably struck in small quantities. At first both the gold and the silver are fine, but towards the close of the empire they are much alloyed. The types, except when they refer simply to the sovereign, are of a religious, and consequently a Christian character. This feeling increases to the last. Thus, on the obverse of the earlier coins the emperors are represented alone, but from about the tenth century they are generally portrayed as aided or supported by some sacred personage or saint. On the reverses of the oldest coins we have such types as a Victory holding a cross, but on those of later ones, a representation of our Saviour or of the Virgin Mary. Subsequently some allegorical religious types are introduced, as that of the Virgin Mary supporting the walls of Constantinople. The principal inscriptions for a long period almost invariably relate to the sovereign, and express his name and titles. The secondary inscriptions of the earlier coins indicate the town at which the piece was struck, and, in the case of the larger copper pieces, the year of the emperor's reign is also given. From about the tenth century there are generally two principal inscriptions, the one relating to the emperor, and the other to the figure of our Saviour. The secondary inscriptions at the same time are descriptive, and are merely abbreviations of the names or titles of the sacred personages near the representations of whom they are placed. From the time of Alexius I., Comnenus, the principal inscriptions are almost disused, and descriptive ones alone given. These are nearly always abbreviations, like the secondary ones of the earlier period. The language of the inscriptions was at first Latin, with a partial use of Greek; about the time of Heraclius, Greek began to take its place on a rude class of coins, probably local; by the ninth century Greek inscriptions occur in the regular coinage; and at the time of Alexius I. Latin wholly disappears. The Greek inscriptions are remarkable for their orthography, which indicates the changes of the language. Of the art of these coins little need be said. It has its importance in illustrating contemporary ecclesiastical art in the East, but is generally inferior to it in both design and execution. The denominations, except those of the gold money, present matter for careful inquiry, little that is definite

¹ The beautiful bust in the British Museum, usually called that of Clytie, probably represents a Roman lady of the early days of the empire. That it is the work of a Græco-Roman artist, and—whether meant to be an ideal subject or not—the portrait of a Roman lady, admits of no doubt. In time it must be, judging from its style, of the first century of the Christian era; and the manner in which the hair is worn points to the earlier part of that period. The lady represented may be only a private person, but the excellence of the work makes it far more probable that she is of an imperial family. On a comparison with the coins, it will be noticed that the head bears a great resemblance to that of Antonia, with whose character the simple modesty of its expression, unexcelled in portrait-sculpture, would well accord. That Antonia is represented on some of these coins as Ceres or Proserpine, agrees with the conceit of the sculptor, who has made the bust to spring from a flower.

Mediæval
and Mo-
dern Coins.

having been ascertained respecting them. The chief gold piece was the *solidus* or *νομίσμα*, which maintained its just weight, as established by Constantine, for near 1000 years from the reign of Anastasius until the latter days of the Empire of the East, and without diminution of purity except during the time of disaster that closed this long period, its corruption commencing under the Comnenian princes. This accuracy rendered the *solidi* famous in the commerce of Europe, so that they were the principal gold pieces, not alone of the East but of the West also, before the issue of florins and ducats by the cities of Italy. The smaller gold pieces were the half and third of the *solidus*, as in the late Roman coinage, but after a time they were both disused, and the *solidus* was alone issued. In the eleventh century the *solidus* begins to be struck in a very concave, or rather a cup-shaped form; and this kind soon supplanted the old flat coin, and continued to the taking of Constantinople. The silver and copper pieces take the same shape, but not so consistently. These concave coins are termed *nummi scyphati*. The silver money of Justinian I. has more denominations than that of the close of the Western Empire, but they are not satisfactorily determined and identified. In the reign of Heraclius, in A.D. 615, a large silver piece, weighing six grams, and therefore called a *hexagram*, was issued: its weight is about 105 grains. During the eleventh century concave silver pieces were issued, as well as flat and somewhat thick ones of a smaller size and lesser weight. The Byzantine copper money falls into two great classes, the first commencing under Anastasius and ending under Basil I., and the other beginning under Leo VI. and extending thence to the close of the empire. The former class is distinguished by the coins bearing numerals indicative of their value. It follows three systems,—that of the empire generally, that of Alexandria, and that of Carthage. The unit was the coin called *νομισμα* or *λεπτον*. Under Justinian I., or about his period, we observe coins of the empire generally, with on the reverses the following indexes of value:—M, K, I, E, Δ, Γ, B, and A, or 40, 20, 10, 5, 4, 3, 2, and 1, *nummia*; the Latin equivalents of certain of these being given on some coins, chiefly of western mints, and the index XXX also occurring without a Greek equivalent. Anastasius, in A.D. 498, reformed the copper coinage, and struck pieces with the index occupying the greater part of the reverse, and having beneath it the abbreviated name of the place of issue. Justinian I. added, in the coinage of his twelfth year, A.D. 538, the regnal year. The weight of this copper money presents extraordinary variations, which indicate the condition of the imperial finances from year to year. There is, as might be expected, a decline which is constant, although irregular. The Alexandrian coins commence under Anastasius, and terminate with the capture of the city by the Muslims. They have two denominations, marked respectively IB and S, as containing 12 and 6 *nummia*, the former of which forms the great bulk of the copper money, and maintains its weight with tolerable accuracy. Some of these pieces of the reign of Heraclius, struck while his sons Heraclius Constantinus and Heraclonas were associated with him, have the double index IB and M, a circumstance explained by the depreciation of the copper money of the empire generally, while that of Alexandria retained almost its just weight. There is an isolated Alexandrian coin of Justinian I., with the index ΔΓ (33), of great rarity: it was probably issued as an experiment, and never subsequently struck. The monetary system of the Vandals at Carthage is an offshoot of the Byzantine. It probably lasted from the accession of Huneric to the capture of the city and dethronement of Gelimer; but the pieces bearing indexes of value have no sovereign's name. The indexes are XLII, XXI, XII, and IIII. The system must be regarded as a double one, comprising a piece of 42 and its half, and one of 12 and its third, the relation of all being, if we take the piece of 12 as the unit, for the sake of convenience, 3·5, 1·75, 1, and ·33. Under Basil I. there was a reform, and larger copper pieces were issued. The second class of Byzantine copper coins begins under Leo VI. The denominations are at first evidently the same as those of the preceding class.

Besides the regular series of the Byzantine Empire, in which

we include the money assigned to the Latin emperors of Constantinople, there are several groups connected with it, either by their similarity, or on this account, and also because the sovereigns were of the imperial houses. The former of these two classes comprehends the money of the Ostrogoths struck in Italy, that of the Vandals in Africa, and that of the Visigoths in Spain. The last series is wholly of gold pieces, which, notwithstanding their barbarism, are of interest, as showing the wealth of the kingdom. The latter class comprises the money of the emperors of Nicæa, of Thessalonica, and of Trebizond. The last group consists of small silver pieces, which were prized for their purity: they were called Comnenian aspers (*ἀσπρες Κομνηνᾶς*), the princes of Trebizond having sprung from the illustrious family of the Comneni. (The best work on the Byzantine coinage generally is M. de Saulcy's *Essai*.¹ The Letters of the Baron Marchant² contain much that is valuable; and the treatise of M. de Pfaffenhoffen on the coins of the empire of Trebizond³ should also be consulted.)

The class comprising the rest of the mediæval money may Other men- now be generally described, before we briefly notice its several divisions with their modern continuations. The oldest of these coins.

coins are imitations, more or less barbarous, of the late Roman and early Byzantine money. They are usually of gold, and represent the *solidus* and its divisions. In Italy, where much of the civilization and art of the Romans yet remained, the coins of the Lombard kings of Italy and dukes of Benevento are not greatly inferior to the contemporary coins of the Greek emperors. In France, the Merovingian sovereigns struck pieces which are sometimes even more faithful imitations than these. Britain, most completely cut off from civilization after the departure of the Romans, first issued barbarous and blind imitations of the smallest Roman copper coins latterly in circulation, and then little silver pieces, with types sometimes of the same origin. In Spain, the gold money of the Visigoths, already mentioned, is in its general character similar to that of the Merovingian kings of France.

A little before the commencement of the German Empire a new class of coins began to be issued, mainly consisting of two denominations,—the *denier*, of silver, derived from the *denarius*; and its half, the *obole*, which was first of silver, but afterwards of billon, and took its name from the *obolus*. These pieces rapidly supplanted the gold currency, although the imitation of the *solidus*, called the *sol d'or* or *soldo d'oro*, and its divisions, continued to be struck in France and Italy. The characteristic money of the middle ages begins with these coins. Though we still perceive the influence of Roman ideas, the effect of a new system is apparent, not alone in the types of many of the pieces, but in the extension of the right of coinage. The principal coins of this class are of the German Empire, of France, of the Scandinavian states, and of England, and commence about the middle of the eighth century, lasting until the revival of art. Except in the empire, the *denier* was almost exclusively struck, and known as the penny or sterling. The coins were issued not alone by the emperors and kings, but also by the ecclesiastical princes and lords; and, except in England, where the right was almost always more restricted, by the feudal lords and the heads of religious houses. The most common types of imperial and regal coins are, for the obverse the bust of the sovereign, and for the reverse what is commonly termed a Greek cross, varying in form, accompanied respectively by the royal name and titles, and the name of the place of mintage, or of the moneypier, or both. The feudal lords and the ecclesiastics gradually adopted badges or distinctive types, those of the former being of a rude heraldic character, those of the latter having a religious meaning, though with a necessary local reference. The religious types also occur on the coins of sovereigns when struck at cathedral towns. Towards the close of the twelfth century the singular pieces called *bracteates* appear. They were issued in Germany, and seem to have been extremely common during the thirteenth and fourteenth centuries, after which period they ceased. They are coins of silver or billon, sometimes large, but very light, and bearing a single design, usually of very barbarous work. From their extreme thinness, they have the appearance of tinfoil impressions of coins. They often do not bear even a

groups.

¹ *Essai de Classification des Suites Monétaires Byzantines*, par F. de Saulcy, 8vo, Metz, 1836 (with a volume of plates).

² *Lettres du Baron Marchant sur la Numismatique et l'Histoire*, nouvelle éd., 8vo, Paris, 1851.

³ *Essai sur les Aspres Comnénats, ou Blancs d'Argent, de Trébizonde*, par F. de Pfaffenhoffen, 4to, Paris, 1847.

edieval single letter, and rarely a full inscription, and there is therefore frequently much difficulty in ascertaining their proper attribution. During the time of the bracteates civic coins commence, issued by imperial cities, or free cities, or by corporations of towns under ecclesiastical or feudal lords.

The first pieces which display any excellence in art are those of Italy, struck for the emperor, or for the various states, in the time of Frederic II. That sovereign's Italian money affords remarkable evidence of the revival of art; but we do not see as great an advance in other countries. From this time, however, or not long afterwards, until the early days of the sixteenth century, there is a constant progress everywhere, and the coins, although they scarcely add to our historical knowledge, are interesting as works of art. The denominations of both gold and silver money are very various, and some have several appellations in different countries when there is not a sufficient change of weight, style, or appearance to justify their being so separated. The basis of all the systems is, however, to be traced to the commercial cities of Italy, from the florins and ducats of which, the former either of gold or silver, the principal coins of other countries were derived. In the middle of the fifteenth century medals commence, and for about a hundred and fifty years are frequently of high merit and interest. It may be mentioned that the mediæval silver coinage is on the whole the most important, the gold almost failing from the time of the decay of Roman influence until that of the revival of art, and the copper being much neglected, and sometimes altogether abandoned, until near the close of the middle ages.

It is not necessary to speak at any length of the general characteristics of the modern coins and medals of European states and their colonies. In all that is technical, as in the preparation of the metals, the convenience of the form, and the mechanical execution, the moderns have far surpassed their predecessors; but in the beauty and meaning of the types they are at as great a distance below them, and immeasurably below the Greeks. The French medals of the first Napoleon are alone in the least comparable with the earlier pieces of the same kind. We will not here enumerate the denominations; but it may be noticed that the sovereign and the dollar, sometimes yielding to the shilling, which may be termed its quarter, all with various appellations, but little difference of weight, are the principal gold and silver coins of both hemispheres.

Art.

It would be interesting, had we space, to notice fully the art of this entire class, to examine its growth, and to trace its decline, but, as with that of Greek and Roman coins, we must limit ourselves to the best period. This is a space of about a hundred and fifty years, from the middle of the fifteenth century to the close of the sixteenth. The numismatic art of this time may not unworthily be placed by the side of its sculpture and its painting. Not alone have some of its medallists taken honourable places in a list where there was no room for ignoble names, but to design medals was not thought an unworthy occupation for the most famous artists. There are, as we should expect, two principal schools, the Italian and the German. The former attained a higher excellence, not alone as possessing a finer style, but one especially adapted to coins or medals. The object which the artists strove to attain was to represent a head, or to commemorate an action, in the best manner possible, without losing sight of the fitness of the designs to the form and use, real or imaginary, of the piece on which they were to be placed. For the successful attainment of this purpose, the style of the later pre-Raphaelites was eminently suited. Its general love of truth, symmetrical grouping, hard drapery, and faithful though cold portraiture, were qualities especially fitted to produce a fine portrait and a good medal. The less sculptural and more pictorial German art was not so suitable to numismatic designs. The portraits of the German coins and medals are often more characteristic than those of the Italian, and the groups have sometimes greater expression; but both are less appropriate. They show also too great a profusion of detail, by which the effect of the boldness of the outlines is frequently lost; yet they

display great originality and vigour, and will reward an attentive study. Both these schools, but especially the Italian, afford the best foundation for a truly excellent modern medallistic art. The Greek and Roman coins are rather to be studied as examples of art in general than of this especial art, although they supply the most useful suggestions. To copy for a modern piece the design of a Greek or Roman coin is as inappropriate as it is to represent an English general in the garb of a Greek hero in one place, and in that of a Roman statesman in another. The finest coins and medals of Italy and Germany have an object far more similar to that we seek to fulfil in our own, and their nearness in time makes many details entirely appropriate. Thus, without blindly imitating them, our artists may derive from them the greatest assistance.

(The most useful works on mediæval and modern coins generally are, Appel's *Repertorium*,¹ the treatises of Mader² and Lelewel;³ and, for current money, the *Encyclopédie Monétaire*.⁴)

We do not purpose to enter in any detail into the various divisions of the subject we have treated in its main outlines. The questions that would require consideration are of two complicated and technical a nature to be illustrated in the present essay within any reasonable limits: our endeavour will therefore be merely to indicate the principal matters of inquiry, and the most serviceable books for the student's use.

The money of Portugal is regal, and not of great interest. It affords indications of the wealth and commercial activity of the state in the early part of the eighteenth century. There is no special work upon it. The coinage of Spain is, almost without exception, regal, but a more curious class than that of Portugal. The coins of the early contemporary kingdoms, such as those of Arragon, and of Castile and Leon, are especially worthy of examination. We may mention, as of a very peculiar character, a large gold piece in the coinage of the latter state, called the *Dobla de la Vanda*, from its bearing the shield of the famous order of knighthood of the Vanda or Band. Of this there are examples assigned to John I. (1379-90) and John II. (1406-54). The money of the sole monarchy is less worthy of notice. The city of Barcelona is represented by coins bearing the names of various kings, except in the case of those issued at the time of the Peninsular war. The medals of Spain are not important. (There is no complete work on mediæval and modern Spanish money, but the catalogue of M. Gaillard, referred to in speaking of the ancient coins of Spain, will be found of service in this department also.)

The coinage of France forms a large series. It begins with the money of the Merovingian dynasty. This consists almost wholly of gold pieces, imitated from those of the late Roman and Byzantine rulers, as already mentioned, the chief denomination in commerce being the tremissis, or third part of the sol d'or (solidus). The coins are rare, and bear either the names of a king and city, or of a moneyer and city. They are of different degrees of barbarism in their art. Under the princes of the Carlovingian dynasty the principal coins are deniers, and after a time oboles also, gold money being extremely rare. They bear the name of the king and that of the city where they were struck, and have a more original character than the earlier pieces, although they are still barbarous. The money of the Capetian house commences with coins like those of the line preceding it. By degrees the coinage improves. In the thirteenth century gold pieces were issued. There are several denominations of these and of silver coins, but to some different names are applied for various types with the same weight, as the *denier Parisis* of Paris, and the *denier Tournois* of Tours. At the time of Philip VI. the coins are fine. The modern coinage may be considered to commence under Henry II., whose portrait is of good work. During this period there is no very remarkable feature in the current money, except the occurrence in the seventeenth century of the pieces of the sort termed *piéd fort*, which we must regard as a kind of patterns. The seigniorial coins of France are, during the middle ages, of considerable importance, though inferior to the similar classes of German and Italian money. The medals are far more interesting than the modern coins. Their interest begins in the age of Louis XIV., but they take a fresh character under the first republic and the reign of Napoleon I. Almost every great event, from the beginning of the power of the emperor until his fall, is worthily commemorated in this series, unequalled in its class for extent, completeness, and excellence. The designs, notwith-

Mediæval
and Mo-
dern coins.

standing that mannerism which appears to be essential to modern French art, are vigorous in drawing, and executed with great care and skill. The intention of each subject is well carried out, if we make the same allowance as before for national peculiarity of feeling; and equal success is shown both in realistic representation and in idealistic composition. No other series of medals is at all to be compared to this, although individual specimens of the mediæval period struck both in Italy and Germany are of a far higher style, more original, more vigorous, and altogether grander both in the idea of the artist and the form which he has given it. (The numismatists of France, especially of late, have displayed a most praiseworthy diligence; so that we cannot indicate a tenth of the useful treatises they have produced. On the regal coinage the works of Le Blanc,¹ and Fougères and Combrousse,² must be mentioned; on the seigniorial, that of Duby;³ and on the Napoleon medals, as we may term them, the volumes devoted to this subject in the series entitled *Trésor de Numismatique et de Glyptique*.⁴)

England.

The English coinage, as before mentioned, commences with two uncertain classes, which, wherever struck, certainly formed the currency of the country during the interval from the departure of the Romans, about A.D. 450, until the issue of money with royal names by the Saxon kings, a practice which cannot be carried earlier than about a century after this event. One of these classes consists of imitations of the latest Roman copper money, and the other of the small silver pieces to which the name of *sceattas* is applied, having rude types which are sometimes of Roman origin, but sometimes original. In all probability the former were first issued, and then the latter. The regular coinage commences under the Heptarchy. There is money of the kingdoms of Kent, Mercia, the East Angles, and Northumbria. The chief coins are silver pennies, but *sceattas* also occur; and of Northumbria there are *stycas*, which are pieces of a base metal in the composition of which copper is the largest ingredient. The most interesting coins of this group are those of Offa, king of Mercia: these are silver pennies, remarkable for their quaint designs and their relatively careful execution. Of this period, but extending into the earlier part of that of the sole monarchs, there are coins issued by the archbishops of Canterbury and York. The money of the sole monarchs, whether Saxons or Danes, is strictly a continuation of that of the Heptarchy: it consists almost wholly of silver pennies, which latterly were cut into halves and quarters to form halfpennies and farthings. Under the Normans and earlier Plantagenets the same coinage continues; but under Edward III. there is regular gold money, of which the chief piece is the noble of six shillings and eightpence; and the silver groat, which supplanted the penny, has already commenced. The obverse-type of the noble, representing the king in a ship, probably commemorates, as suggested by Ruding,⁵ Edward's victory over the French fleet off Sluys, A.D. 1340. At the same time, there is a visible improvement in the art of the coinage, which advances until, under the early Tudors, it attains its highest excellence, from which, however, it is speedily to fall. Of Henry VIII. we have gold and silver coins of most existing denominations, as well as of earlier ones long since abandoned. The finest piece is the sovereign, a large flat coin of gold, bearing on its obverse the figure of the king (whence its name) on his throne. With Queen Elizabeth the modern money may be held to commence, the Gothic character of the types giving place to the later and far less beautiful style. The coinage of Charles I. presents great varieties, owing to the civil war. The scarcity of silver in the royal treasury during the troubles induced the king to coin twenty and ten shilling pieces of silver, in addition to the crowns and smaller denominations. One of the most remarkable of his pieces is a crown struck at Oxford. It bears on the obverse the king on horseback, with beneath the horse a representation of the town, or rather of its principal buildings, and on the reverse the heads of the "Oxford Declaration." Of equal interest are the siege-pieces of many castles famous in the annals of those days. The coinage of the Commonwealth is of a plainness proper to the principles of those who sanctioned it. The great Protector, however, caused to be designed money of his own bearing his head. This seems never to have been sent forth, and is therefore put in the

class of patterns. Simon, the chief of English medallists, designed the coins, which are unequalled in our whole series for the vigour of the portrait (a worthy presentment of the head of Cromwell), and the beauty and fitness of every portion of the work. Henceforward there is a decline in the coinage, although skill is perceived in the portrait of William III., whose grand features could scarcely have failed to stimulate an artist to more than a common effort. Queen Anne's money is also worthy of note, since one of her coins, the farthing, has been the cause of an extraordinary delusion. It is commonly imagined that a very small number (some say three) of these pieces were struck, and that their value is a thousand pounds each, instead of a few shillings. In consequence, many imitations have been forged, and such are constantly brought to collectors by unfortunate labourers and the like, who imagine that they possess the greatest numismatic treasure in the world. After this there is little to remark, except the baseness of the art of the coins under the first three Georges, until the genius of Pistrucci gave a worthier form to our currency, which the care and accuracy of Wyon has preserved without mere imitation. Besides the regal coinage, there is scarcely any baronial money, the class being represented by a few pieces, generally at least struck by personages of the royal house, and all belonging to the period of the close of the Norman line and beginning of the Plantagenet. The English tokens form a curious class. They are of two periods: the earlier, which are generally of brass, were issued at the middle of the seventeenth century and somewhat after; the later, which are mainly of copper, were struck during the scarcity of the royal coinage at the end of the last century, and during the earlier years of the present one. Both were chiefly coined by tradesmen, and bear their names. The medals of England are less important than those of France and Germany. Some of those of the Tudors, commencing with Henry VIII., are of good style. Those of the period of the Stuarts are more interesting than beautiful. During the civil war many pieces were struck commemorating the chief men and events of that time. The custom continued under the Commonwealth and after the Restoration; and there is a curious series of medals and what may be termed jetons, relating to the Popish Plot in the reign of Charles II. Of a later period are the medals of the two Pretenders and their family; but of our own times little worthy of note. The colonial money of England is unimportant until lately, when it is not unworthy of the wealth and activity of the dependencies. The money struck by the English kings for their French dominions forms a peculiar class, mainly French in its character, termed the Anglo-Gallic. This may be used to supply some gaps in the regal series of England, as, for instance, containing money of Richard I., of whom no English coins are known. (On the English coinage generally there is the great treatise of Ruding;⁶ on the silver money, the very complete and accurate work of Mr Hawkins;⁷ on the Anglo-Gallic coins, Gen. Ainslie's Essay;⁸ on the medals, nothing better than the indifferent work of Pinkerton;⁹ and on the tokens of the seventeenth century, a catalogue just published, which entirely meets the wants of the collector.¹⁰)

The coinage of Scotland is allied to that of England, although Scotland generally ruder; but it seems to have been more influenced in the early period from Scandinavia, and towards its close from France. The oldest pieces are probably silver pennies or sterlings, resembling the contemporary English money, of the commencement of the twelfth century. In the fifteenth and sixteenth centuries there is an important coinage, both in gold and silver, not the least interesting pieces being those of Queen Mary, many of which bear her portrait. The indifferent execution of the coins of this period is traceable to the disturbed state of the kingdom. (On the coinage of Scotland there is the old work of Cardonnel,¹¹ and the later one of Mr Lindsay.¹²)

The money of Ireland is more scanty and of less importance than Ireland. that of Scotland. The pieces most worthy of notice are the silver pennies of the early Norse kings. Of later times there is little that is interesting, except the coinage of James II. during his attempt to maintain himself in the island. (Mr Lindsay has written a work on the Irish coinage.¹³)

Belgium occupies the next place in our arrangement. Its Belgium and Hol-land.

Mediæval
and Mo-
dern Coins.

coinage comprises many pieces struck by foreign rulers, and has little of an independent character, either in the regal or seigneurial class. It closely resembles the money of France and Germany. The series of Holland is similar in character until the period of the revolt of the Provinces. The medals are highly interesting, more especially those which were struck by the Protestants in commemoration of current events, many of which relate to the great contest with Spain. Such are the pieces recording the raising of the siege of Leyden, likened to the destruction of Sennacherib's army; the assassination of William the Silent; and the discomfiture of the Armada; affording striking indications of the zeal, the piety, and the confidence in the right which built up the great political structure of the Dutch Republic. After this time the medals lose much of their interest. (Among the many works on the coins of the Netherlands and Holland, we must specify that of Van der Chijs.¹)

Switzer-
land.

The money of Switzerland is of considerable importance, chiefly during the early period of its independence. The coins of both cantons and towns bear their ancient shields, drawn at first with a vigorous grotesqueness. There are also pieces of ecclesiastical lords, and others having the right of coinage in particular cities or districts. (The general works on German coins will be found to treat of those of Switzerland also, but we must mention the special essays of Haller² and Dr H. Meyer.³)

Italy.

The coinage of Italy during the mediæval period is alone rivalled by that of Germany, which, moreover, it excels in some respects. First in Italy the revival of art influenced the coins, and in Italy each step of advance found in them its record. The oldest mediæval Italian coins are gold pieces of the Lombard kings of Italy and of the dukes of Benevento, occupying, as already mentioned, very much the same position in relation to the late Roman and the Byzantine money, as the earliest coins of Spain and France. The series of the kings of Italy is taken up by that of the emperors of Germany, which forms a remarkable class, especially as indicating the excellence of art here at a time when to the rest of Europe it was almost unknown. The great republics are worthily represented, their coins attesting by their purity, and the influence they seem to have exerted, the commercial energy of the states. Of Venice there is a long series, for the chief part bearing the names of the doges. Florence contends with Venice in the extent and purity of her coinage. Her florins of gold were for a great period as famous in European commerce as the gold ducats and silver matapans of her rival. The types of the florins—the lily of Florence, and the Baptist—were copied by the feudal lords of more northern lands, to the swamps of Holland and the shores of the Atlantic; the designs of the matapans—one of which, the doge receiving the gonfalone from St Mark, was yet more distinctive—were adopted by the half-barbarous tribes whose territories were the fighting-ground in the long contest of the German and the Turk. The medals of Florence, which are anterior to the time of the dukes, or those issued by them, not to omit the works of Florentine medallists which are not otherwise connected with their native state, are among the chief monuments of the numismatic art of Italy. The chief value of these medals lies in their bearing admirable portraits of persons of celebrity. Passing southwards, the series of Rome is of the highest historical and artistic value. It is for the greatest part struck by the popes, of whom there are both coins and medals. The later pieces commemorate the events of each reign, and are, as might be expected, of high excellence in style, although, from the excessive fondness of the artists for allegory, they are generally wanting in simplicity, and do not directly seize the attention. Another fault is partiality without invention or vigour. We may instance the medal of Gregory XIII. recording the Massacre of St Bartholomew, both for its reverse-type, an angel slaying the Huguenots, and the inscription VGONOTTORVM STRAGES. Far superior is the satire of some of the medals of the Dutch Protestants, and the dignity of others. Since the seventeenth century, few papal medals have been struck that are entitled to even moderate praise; those of the present day are beyond measure poor and weak. We must also mention the money of Naples, especially the oldest, which is of its strong Norman princes, who, supplanting the Arabs in Sicily,

at first there struck their coins with legends partly or wholly in Arabic characters, while on the mainland they issued the ordinary money of the day. Many other groups might be mentioned, as the coins of the Visconti and Sforza families of Milan, of the D'Esté of Ferrara, and many more houses great in their love of arms and in their protection of art. (The coinage of Italy is amply illustrated by excellent essays, mainly of the last century. We must particularize those of Argelati,⁴ Zanetti,⁵ Bellini,⁶ Carli-Rubbi,⁷ and Fioravanti.⁸)

The money of Germany is, like that of Italy, far too various for Germany. us to be able to do more than sketch some of its main features. It comprises three great classes,—the coinage of the emperors, that of the electors, and that of the smaller princes, the religious houses, and the towns. The imperial money, even when limited to what is strictly German by the exclusion of pieces struck in France and Italy, forms a very large series. Its chief characteristics are the same as those of the other great mediæval classes, except that, until near the close of the middle ages, it is considerably backward in its art. At this time its portraits are very characteristic, as well as the current coins as on the medals and the double-dollars, which are virtually medals. Of especial excellence is the medal of Maximilian I. and Mary of Burgundy, struck on their marriage; and the still finer medal of Maximilian, bearing on its obverse the emperor on horseback, fully armed, and said to have been designed by Albert Dürer, of whose hand it is not unworthy. The coinage of the archbishops of Cologne is a remarkable series. In the earlier period it bears representations of the cathedral, as is not unusual on ecclesiastical money of the time. The coins of Mayence, although they yield to those of Cologne in number and importance, form a large group. Of the dukes of Saxony there are fine dollars, which, at the period of the Reformation, bear vigorous and characteristic portraits. Of Treves there is another curious class, resembling that of Cologne. Besides these, there are very numerous bracteates and later pieces of temporal lords, of bishops and abbots, and of cities, some of which are free. (The treatises on this branch are many and excellent. We must specify those of Joachim⁹ and Cappe,¹⁰ besides remarking that the general works of Mader and Appel, before mentioned, give very large information on German money.)

The coins of the Scandinavian states—Denmark, Norway, and Denmark, Sweden—are almost wholly regal. There are a few civic pieces, but Norway, the ecclesiastical bracteates assigned to this group are probably and Sweden for the most part of Northern Germany. The regal money of these states is closely connected. In the earlier period it resembles the English and Scottish coinage, although with a national character of its own; afterwards it is more like that of Germany. There are some medals of historical interest. (This branch has not received the attention it merits, and there is no complete essay upon it. The great Danish work on medals, however, will be found to contain very full materials.¹¹)

The coinage of Russia is mainly of the modern period, and, until Russia. comparatively recent times, shows a remarkable degree of barbarism. The medals are of no intrinsic merit, their sole value being historical. Both coins and medals are regal, except such of the former as were struck in cities now included in Russia, while yet under Sweden. (The work of Baron de Chaudoir will be found to give a good account of Russian money.¹²) The coins of Poland are mainly of the kings, and resemble those of the Hungarian kingdom. Of the states between Germany and Turkey there are interesting coins. The kingdom of Hungary and the principality of Transylvania are each represented by an important series, that of the latter comprising large and remarkable gold pieces of the sixteenth and seventeenth centuries. There are early coins of the patriarchs of Aquileia, and of the kings of Servia. The money of the Turkish Empire is of the oriental class, but there are many coins struck by Christian states in its present territories. This class may be called that of the Crusaders, comprising money of the princes of Achaia, and the dukes of Athens, in Europe; and of the kings of Cyprus and Jerusalem, the princes of Antioch, and the counts of Idessa and Tripolis, in Asia. This is very similar to the contemporary mediæval money. A kindred series is that of the knights of Rhodes and Malta, which bears testimony to the wealth and power of that

America.

illustrious order. (We must mention, in illustration of this group, M. De Saulcy's account of the money of the Crusaders.¹)

Respecting the coinage of America it is needless to enter into detail. Neither the money of the Spanish and Portuguese dependencies, and of the later states, nor that of the English colonies and the United States, present much that is worthy of note. The coinage resembles that of the parent countries, but is of coarser work. The dollar is the chief denomination. There are some coins of historical value, as those with the portrait of the Mexican emperor Augustin; and in the north, Lord Baltimore's pennies. (The *Encyclopédie Monétaire*, before mentioned among general works, will be found to be of great use in this branch.)

SECT. VI.—ORIENTAL COINS.

Oriental coins are of two great classes, the Pagan and the Mohammadan. (On both classes the great work of Marsden should be consulted.²) The first division is separated into the coins of the Persian Empire, the Parthians, and the Sassanians; of Bactria, and of the Hindus; and into those of transganges India, China, and Japan.

Persian
imperial
coins.

The Persian coins probably range from the commencement of the reign of Cyrus, or his capture of Babylon, to the overthrow of the empire by Alexander the Great, a period of about two centuries. The only pieces we can positively attribute are of satraps of the later kings. There can be no doubt, however, that we possess specimens of almost every reign, except the very short ones, from that of Cambyzes, to which, if not to that of Cyrus, the oldest coins must be referred, from their style. The metals are gold and silver, the latter being that of the great bulk of the coinage. The form is usually flat and very thick. The types are of no great number. The main principle on which they were selected was a desire to honour the sovereign, which, if we recollect the worship the Achæmenian kings received, is not greatly different from the religious feeling of the Greek coinage. The chief observe-types represent the king in a chariot, sometimes hunting the lion, or as an archer drawing his bow. This personage is not, however, to be supposed in any case to be the reigning king, but rather the King of Persia in a kind of abstract sense. As a reverse to these types we notice occasionally a city or a galley. The money of the satraps is somewhat more Greek in its character, although it has among its types the representation of a king or satrap, that of a city, and the eastern device of a lion seizing a bull, and the like. The undoubted regal coins have generally no inscription whatever. Some, seemingly of this class, though they are perhaps of satraps, bear Phœnician characters, apparently the beginning of a name in one case, and in another, various dates. The coins of satraps have Phœnician inscriptions, usually giving the name of the person who issued the money, and that of the divinity of the place where it was struck. The art of this class of coins is not remarkable; it is at first similar to contemporary Greek art, and generally maintains, at least in some degree, its original conventional stiffness. There is one exception to this character in a beautiful coin attributed to Cyrus the Younger, to be soon mentioned, but this is in all respects a Greek piece, though evidently struck for a Persian king or usurper. The Persian coins are adjusted to the Phœnician talent. The principal denomination of the gold is the daric or daric stater. The chief silver coin is a third of the tetradrachm, a denomination which is not uncommon; and there are also octodrachms, as well as smaller pieces.

Coins of
the Persian
kings and
satraps.

We will notice some of the principal coins, first of the kings, and then of the satraps, in chronological order, as far as this is practicable. The oldest Persian pieces are probably certain octodrachms of very early work. They bear on the obverse a galley beneath the walls of a town, and on the reverse the king in his chariot engaged in a lion-hunt. These can scarcely be later than the age of Cyrus or Cambyzes; and it is most reasonable to suppose them to have been struck at Tyre. Next in time to these we would place the pieces with semi-Egyptian types, having on the one side an owl with a crook and flail, like the representations of Egyptian sacred hawks, and usually on the other a king or divinity riding upon a kind of sea-horse. The latter is sometimes the obverse-type. These we take to be the coins of Aryandes, satrap of Egypt, whom Herodotus relates to have been put to death by Darius Hystaspis for striking silver money; but they may perhaps be regal pieces. After these may be placed the gold darics and the

silver pieces of the same type, and two-thirds of their weight, with the figure of the king, usually as an archer kneeling, on the obverse, and with an irregular incuse type on the reverse. These, or at least the gold coins, appear to have been current as late as the time of Artaxerxes Mnemon. To this reign we may assign, on strong evidence, a most remarkable coin, bearing the portrait of a Persian regal person on the obverse, and on the reverse a lyre, with the inscription BAZIA. This is assigned by M. de Longpérier to Cyrus the Younger; and we accept his attribution as highly probable. Of the money of the satraps we may particularize the coins of Pharnabazus and Tiribazus, and those formerly attributed to Darnes, but given by Mr Waddington to the celebrated Datames. (The best work on the ancient Persian money is that of the Duc de Luynes on the coins of the satraps.³)

Oriental
Coins.

After eighty years of subjection, first to Alexander and his successors, and then to the earliest Bactrian kings, the Persian power was restored by Arsaces. With him the Parthian series of coins commences. This consists mainly of silver money, though there are also copper pieces. It shows markedly the influence of the Greeks, having inscriptions in their language, and its reverse-types derived from their coinage. The obverses bear the sovereigns' busts, which in the earlier period are often well executed. The denominations appear to be wholly of Greek origin. The Parthians were succeeded by the Sassanian princes. This line issued a more oriental coinage than their predecessors, bearing on the obverse the king's bust, usually wearing a very large and elaborate head-dress, and on the reverse the sacred fire-altar. The attachment which Ardeshir, the founder of this dynasty, bore towards the fire-worship, established this national reverse-type, which endured during the four hundred years that his house held the sovereignty. The Sassanian money is chiefly of silver; gold pieces are very rare. (On the Parthian coins the work of Mr Lindsay⁴ should be consulted; on the Sassanian, M. de Longpérier's treatise.⁵)

The Bactrian coins form an important link between the money of the West and that of the East. They were issued by the princes of one of the dynasties founded on the ruins of Alexander's empire, in so distant a territory that its very existence was scarcely known until the discovery of the coins. This kingdom was established B.C. 256, in the reign of Antiochus II., king of Syria, by the defection of Diodotus, governor of Bactria. The coinage of this first sovereign evidently follows that of the Seleucidæ in types and inscriptions, and, so far as the silver is concerned, in weight also; and the principal money of the subsequent rulers is of the same kind, although showing decay in its art. Under Agathocles, however, who seems to have been the successor of Diodotus, and certainly cannot have reigned much later, we observe the commencement of a peculiar class of coins, consisting of square copper pieces, bearing on the one side a Greek inscription, and on the other an Indian-Pali legend. The occurrence at this early period, in the midst of a Greek coinage, of pieces of a form unknown to the Greeks, and with an Indian as well as a Greek inscription, furnishes, as Mr Thomas argues, no weak evidence of an independent Indian coinage before this time—a subject to which we shall shortly recur. The Bactrian series is chiefly valuable from the aid it has afforded in the reconstruction of contemporary history. Much, however, remains to be done in the arrangement of the series before its full use can be realized. Of the coins of the successors of the kings already mentioned little need here be said, except that bilingual inscriptions become constant on silver as well as copper pieces, and that the former are sometimes of the square form. The Bactrian series is succeeded by more than one half-barbarous class similar to it, but far more oriental in character.

The question of the independence of the earliest Indian coinage is of too complicated a nature to admit of its being here fully discussed, but we must indicate its main features in order to draw attention to a matter affecting ancient civilization in the far East. It must not be supposed, however, that the conclusion that the Indians had struck money before the time of Alexander, would attribute to them the separate invention of coinage: in this case it is more reasonable to presume that they had received Greek coins in commerce, and had thus been stimulated to issue a metal currency of their own. Mr Thomas has devoted much attention to this question, which will be found to be fully discussed in his edition of Prinsep's *Essays*. He argues on the existence of the square copper pieces in the Bactrian series, on the character of antiquity displayed by the Behâ copper coins, and on the presumptive evidence of written records. The earliest class he considers to be that of silver

Oriental
Coins.

punch-marked pieces. Of a later period than this whole class are the coins of the Sah kings of Saurashtra, the age of which is far more nearly fixed. These are silver pieces bearing dates which show them to have been struck within about a hundred years. The dates Mr Thomas considers to be reckoned from the Sri Harsha Era, which would place the coins between the middle of the second and the middle of the first century B.C. The Sah kings were followed by the Guptas, who appear to have been at the first contemporary with them. To these belong the rude gold coins, with figures of Indian divinities, which are frequently found in the country. Their importance at the time, and their influence on the later coinage, must have been very great. The types of the later Hindu coins are of the same character as those of this group, although recently better executed. Although they are still issued, these proper Hindu coins have been long since virtually supplanted by those of the Mohammadan dynasties and the Company. (The most useful works on Bactrian and Indian money are Prinsep's *Numismatic Essays*, which have been collected and edited by Mr Thomas, and will be very shortly published. The original value of these papers is greatly enhanced by the labour and skill with which Mr Thomas has illustrated them, bringing them down to the present state of knowledge, and adding everywhere new information. Professor Wilson's *Ariana Antiqua*¹ must also be consulted. The most complete account, though one now requiring many additions, is in Marsden's great work, which we have already mentioned.)

Siam and
China.

Beyond India, it may be mentioned that Siam has a coinage of its own, consisting of spherical lumps of silver, impressed with a punch, in the place of which coins with oriental types, but on a European model both in form and art, are now being issued. The Chinese money offers a field for great research. Here the question of an origin of money in the East, independently of Greek influence, is raised by the great antiquity that the Chinese writers assign to the commencement of the art among them. The conclusion, for the present at least, must here mainly depend upon our estimate of the value of the written evidence, for the money affords but doubtful testimony, more especially as the Chinese fabricate coins as they do vases, to deceive the curious. Some existing specimens are attributed to the twenty-first year (B.C. 523) of the reign of the Emperor King-wang, of the Tcheow Dynasty; but in the opinion of the Baron de Chaudoir, there is no certainty, before the reign of Chy-hoang-ty (B.C. 247-210), of the Heow-tsin Dynasty. The money consists almost wholly of copper pieces. These are at first of various shapes, sometimes being in the form of a sword or a bell, though flat; but at length they take the usual shape of coins, except that they are perforated in the centre with a square hole, in order that they may be strung. The silver coins are dollars of a recent period. The rebels have issued copper money resembling that of the Mantchoo Dynasty, but with their own inscriptions. (On the Chinese coins, Baron de Chaudoir's work should be consulted.²)

Moham-
dan coins.

The second class of oriental money—that of Mohammadan states—has been issued during a period extending from about the middle of the seventh century of the Christian Era to the present day. The oldest of positive date (gold coins) were struck A.H. 78. There are others, however (copper pieces), which must be ascribed to the interval between this date and the first great extension of Arab power, half a century earlier. We may mention the bilingual coins of cities of Syria and Palestine, Damascus, Emesa, and Tiberias, and barbarous imitations of the latest Byzantine money of Alexandria. Silver pieces are known of the year A.H. 79, but the dated copper coins do not commence until some years later: thenceforward the coinage of the greater number of Muslim states is in the three metals. The date of the earliest gold and silver coins thus falls into the reign of the Khaleefeh 'Abd-El-Melik Ibn-Marwân, under whom, in A.H. 76, the first Muslim coinage is related to have appeared, by El-Mekeen, Es-Suyootee, and Ibn Kuteybeh. There is a remarkable copper coin, generally resembling the bilingual pieces just mentioned, and having on one side a figure, probably representing the khaleefeh. In its inscriptions, which are wholly in Arabic, we read, "The servant of God (or 'Abd-Allah), 'Abd-El-Melik, the Prince of the Faithful."—The fabric and general appearance of the regular coins, especially for the first five centuries of their issue, is remarkably similar. They are always flat,

Oriental
Coins.

and generally thin, and are without types, in the ordinary sense of the term, except some semi-barbarous ones, which originated in imitation of those of the current Byzantine money of the time, or of older Greek types. The whole of both sides of the coins is occupied by inscriptions, usually arranged horizontally in the areas, and in single or double bands around. With the rise of the Tatar power the old Arab type of the coins begins to be disused, and a new one introduced, mainly differing in the greater size of the pieces and the disposition of the inscriptions, which are placed in and around a square. This form was scarcely less wide in its use, or long in its duration, than that which it superseded. The prevalent metal of the earlier class is gold; of the later, silver. The intention of the inscriptions is religious. All Mohammadan coins bear the profession of the faith—"There is no deity but God: Mohammad is the apostle of God." The Shiya'ees add—"Alee is the friend of God." The title of the khaleefeh, and afterwards his name also, or the name and title of the king, as well as the year of the Flight and the place of mintage, are generally given. The religious feeling as to the coinage was, until recent times, not less strong with the Muslims than with the ancient Greeks. For some centuries it was not lawful to put the name of any sovereign, as such, upon the coins, except that of the khaleefeh; and an independent prince, even if actually at war with him, continued to issue money in his name, doing no more than add his own, without any title, as though he were a provincial governor. The rival khaleefehs in Spain and Africa by degrees shook this privilege, and under the Turkish and Tatar dynasties it ceased, about the time when the khaleefehs of Baghdád had nearly lost all temporal power, shortly before their overthrow.

Mohammadan coins cannot lay claim as a class to high artistic excellence. Their beauty depends, in the earlier period, upon the disposition of the inscriptions, and afterwards upon this combined with the form of the characters. Among the best of the older coins are those of the Umawee and 'Abbásee khaleefehs, and of the Fátímee khaleefehs in Egypt. The money of the Moors in Spain, of some of the later kings of Persia, and sultáns of Turkey, affords beautiful specimens of the more recent coinage. The finest, however, are generally inferior in execution, and often in design, to the best engraved work of the same times. The principal denominations, particularly during the earlier period, are well known. For many centuries there were scarcely any more pieces than one of each metal, the *deenár* of gold, the *dirhem* of silver, and the *fels* of copper,—and these were of nearly the same size, and otherwise very similar in their appearance. Their names betray a foreign origin; the *deenár* derived its appellation from the *denarius*; the *dirhem*, from the *drachma*; and the *fels*, from the *folles*. In its weight the *deenár*, at first of about 65.5 grains, followed that of the *solidus*, which at that time had succeeded to the aureus, and was doubtless the "piece of gold." The *dirhem*, of 45 grains, probably was considered as equivalent to the chief silver coin of the Isaurian family. The *fels*, however, cannot be readily identified, from the irregularity of the contemporary copper money of the Byzantines. At a later time, as the influence of the Eastern Empire wore out, the money of the commercial states of Italy affected the oriental coinages; and from this and other causes new systems took their rise, until in our own days the money of the Mohammadan dominions on the Mediterranean is generally assimilated to that of Christian Europe. (The most useful books on Mohammadan coins in general are, besides Marsden's *Numismata Orientalia*, the works of Fráhn³, Moller⁴, and Erdmann.⁵)

The coinage of the Umawee and 'Abbásee khaleefehs merits the same place in this series as the Byzantine in the mediæval. It presents little matter of historical interest beyond the indications of the condition of the state, from the abundance or the scantiness, or even the entire absence, of money under particular reigns. Thus we have evidence of the magnificence of the earliest princes of the house of El-'Abbás, and the misery of the latest, who yet held rule in the city of Baghdád, when the Tatar Hulágu was almost at its doors. Here and there the attention is fixed by a more definite fact, as when on the coins of Hároon Er-Rasheed we read the name of his famous vezzeer Jaafar.

First among the Muslims of Africa and Western Europe we would place the khaleefehs of Spain, who in that remote country restored somewhat of the greatness of their ancestors of the house

Nun
||
Nundinæ.

of Umeiyeh. Their money resembles that of the contemporary 'Abbāsees. Under later dynasties, and especially that of the opulent and luxurious kings of Granada, large gold pieces were issued, noticeable for the fineness of their work. The coinage of the shereefs (or khaleefehs, as they have called themselves) of Morocco or Fez, of the Aghlabee Dynasty, and of the Fātimee khaleefehs at Keyrawān, before they had conquered Egypt, offers little to detain us. The money of Egypt itself forms a long series, well deserving of study. There is nothing remarkable of the period during which it was governed by the nāibs or lieutenants of the Umawee and 'Abbāsee khaleefehs, before the establishment of the independent dynasty of the Toolooneeyeh, A.D. 868. Of this house, and that of the Ikhsheedeeyeh, which succeeded it after a short interval, there are deenārs bearing the name of the reigning prince, besides that of the khaleefeh. The gold money of the Fātimee khaleefehs, who overthrew the line last mentioned, is well executed, and usually has two or three concentric inscriptions on each side. Under the Kurd or Eiyoobee Dynasty the coinage is similar; but under the two Memlook dynasties—the Turkish and the Circassian—the money is coarse, and rather resembles that of the Seljuks than the earlier series of Egypt. Since the Turkish conquest the money of this country has been similar to that of Constantinople, although possessing peculiar characteristics. In Syria there are coins of the Eiyoobee princes. Next to these we may place the money of the Seljuks and Turkuman Ortokites, the latter remarkable for the use of barbarous figures, derived from the Byzantine or ancient Greek types. The coins of the Atabegs form a group similar to the last. The money of the Turkish Empire shows the

influence of the Italian republics. Its principal gold coin at the first was the *funduk*, of about 54 grains in weight, which was derived from the Venetian *sequin* or gold ducat, that, from the time of the decline of the credit of the Byzantine solidi, formed a principal coin of Western Asia. In recent times the money of the sultans of Turkey is of elegant work, although generally not of pure metal.

The Persian coinage does not greatly differ from the contemporary money of the more western states. It may be said to commence under the powerful Samānee Dynasty, and to continue under the Soofees, and Nādir Shah and his successors. The most characteristic part of the coinage is the latest, in which we observe great beauty in the form of the letters and the ornaments, and an unusual variety of types. Among the latter may be noticed one of some gold coins of Fet-h 'Alee Shah, representing the king on horseback slaying a lion; and those of the copper pieces of uncertain date, one of which reproduces the ancient Persian device of the lion seizing the bull. The coins of the Mogul Tatars of Persia, of Teemoor, and of the Khans of Kapchak, resemble the contemporary Mohammadan coinage of other countries. The money of the Muslim dynasties of India forms a considerable class, although it must yield in importance to that of the Hindus. The chief series is that of the Patan or Afghān sultāns, and their successors the Mogul emperors. Among the minor groups we must notice the money of Tipoo Sultān, some of whose coins are very beautiful; and that of the kings of Oude, latterly remarkable for its grotesque imitation of modern heraldry. (This branch of Indian numismatics is treated of in the works before indicated as describing Mohammadan coins generally.) (R. S. P.)

NUN, or AKASSA, a river of Morocco, forming part of the southern boundary of that country. It rises in the Atlas range, and flows westward to the Atlantic, into which it discharges itself, 30 miles S.W. of Cape Nun, after a course of 130 miles.

NEN, or NON, a promontory of Morocco, in N. Lat. 28. 46., W. Long. 11. 3.

NUN, NONN, or NOMN, a river of the Chinese Empire, rises in Manchooria, flows generally southwards, forming part of the boundary between Manchooria and Mongolia, and falls into the Songari, an affluent of the Amur. Its length is about 600 miles, and its chief tributaries are the Hoojur, Noomin, Yalo, Tchola, and Toro.

NUNS, in the Roman Catholic Church, are female ascetics, who, like the monks of the other sex, retire from the world, form themselves into religious communities, and profess perpetual chastity. There are various orders of nuns; some devoting themselves entirely to private religious exercises, while others engage in the more active duties of Christian charity. The first nunnery is said to have been founded by one St Syncletica, a contemporary of St Anthony, in the third century. (See MONACHISM.) The first institution of the kind in France was founded near Poitiers by St Marcellina A.D. 360; and the first established in England owed its origin, according to Dugdale, to Edbald, king of Kent, who founded a nunnery at Folkestone A.D. 630.

NUNCIO (Lat. *nuntius*; It. *nunzio*) signifies a messenger in general, but is employed specially to designate the ambassador sent by the Pope to Roman Catholic states. This functionary is usually a prelate, and when a cardinal he is styled *legate*. In those countries subject to the decretals and discipline of the Council of Trent, the papal nuncios act as judges of appeal from the decision of the bishops; but in other Roman Catholic states (as France, Austria, &c.), which maintain their independency of the discipline of the Court of Rome, nuncios possess no jurisdiction, and have simply the diplomatic character of any other ambassador from a foreign court. In former times, however, the influence of nuncios and legates at foreign courts was frequently all but supreme.

NUNDINÆ, as if *Novendinæ*, from *novem* and *dies*, signifying literally the ninth day, was the name given to the weekly market-days of Rome. The term was also

occasionally extended to the place and business of these markets, as well as to the time at which they occurred. According to the ancient *Calendaria*, the entire year, beginning with the first of January, was divided into weeks of eight days each. Seven ordinary days would therefore always intervene between the last day of one week and the last day of the week immediately succeeding it. To these seven days, the Romans, after their customary mode of reckoning, added, not only the one immediately succeeding, but also the one immediately preceding, which made in all *nine* days, and hence they spoke of the market-day as occurring on the ninth day. A similar usage is still known in some countries where the expression "eight days" is frequently used for a week. Some affirm that the institution of the *nundinæ* owes its origin to Romulus, while others attribute it to Servius Tullius. As, however, the *nundinæ* were originally market-days for the country people, who, on these stated occasions, came to Rome to dispose of the produce of their labour, to provide themselves with necessaries, and to get their legal disputes adjusted by the king, it would seem to follow that the *nundinæ* must have originated at a time when the Roman population extended beyond the precincts of the city. The *nundinæ* were *dies nefasti* for the patricians, and *fasti* for the plebeians (Niebuhr's *Roman History*, vol. ii.); but when such a distinction arose does not appear, for, according to the ancient *Calendaria*, the *nundinæ* and *dies fasti*, or days of business, coincided. For the plebeians, however, the *nundinæ* continued to be business days, and on these they pled causes and held public meetings and debates with members of their own order on matters concerning the public or private interests of that order.

The Romans were always peculiarly careful lest the *nundinæ* should fall on the kalends of January, or on the nones of any month; and to avoid such an unfortunate conjunction, they were particularly watchful in the insertion of the *dies intercalaris*, or the 355th day of the Roman year. The *primæ kalendæ* were avoided, according to Macrobius, from the public belief that, if the *nundinæ* occurred then, the whole of the ensuing year would be signalized by misfortune; and the nones were shunned because the birth-day of Servius Tullius was celebrated on the nones of every month, and the presence of the country folk in the city on that occasion was deemed by the patri-

Nundinæ.

Nuneaton. cians to be dangerous to the peace of the republic, owing to the excitability incidental to such a concourse of the plebeian order. Perhaps, however, more satisfactory grounds for this prejudice were to be found in the fact, that the kalends of January were observed as occasions of intimate domestic intercourse, and that the nones were believed to want the protection of the Deity.

NUNEATON, a market-town and parish of England, county of Warwick, on the left bank of the Anker, here crossed by two bridges, 14 miles N.W. of Rugby, and 17 N.N.E. of Warwick. It is well built, consisting of one main and several smaller streets. The parish church is a small but neat building, in the Gothic style, with a square tower. There are also places of worship for Independents, Wesleyans, Baptists, and Roman Catholics, as well as several schools. The chief manufacture is that of ribbons; but malting and silk-making are also carried on. In the neighbourhood are coal mines and stone quarries; and near the west of the town runs the Coventry Canal. The market-day is Saturday; and three yearly cattle fairs are held. Pop. (1851) 4859.

NUNEZ, or NONIUS, FERNANDO, an eminent classical editor, was born in the latter half of the fourteenth century at Valladolid, and was surnamed "El Pinciano," from *Pintia*, the ancient name of his native town. Though a scion of the noble family of Guzman, and a commander of the Order of Santiago, he consecrated his life to the pursuits of polite literature. After sitting at the feet of the eminent Antonio Lebrija, he studied for some time at Bologna, and returned to Spain the first Greek scholar of his age. His talents were soon employed, at the request of Cardinal Ximenes, in preparing the Latin version of the Septuagint for the Complutensian Polyglott. He was then installed by the same munificent patron of letters in the Greek chair of the newly-founded university of Alcalá de Henares. This office the force of circumstances induced him in course of time to abandon; and he was next appointed professor of rhetoric at Salamanca. It was there that those services in the cause of letters were chiefly performed which elicited the commendation of such men as Erasmus, Lipsius, and Vossius. The annotations that he published in 1536 on the works of Seneca restored the text of that author. He also produced *Observationes in Pomponium Melam*, 8vo, Salamanca, 1543; and *Observationes in Loca Obscura et Depravata Historiæ Naturalis C. Plinii*, Salamanca, 1544. At the same time, both from the academical chair and at his hospitable table, he was instructing many a young man that was destined to spread abroad the light of learning. He died in 1553, requesting that the following words might be inscribed on his tomb: *Maximum vitæ bonum mors*—"The greatest blessing in life is death").

NUNEZ, or Nonius, Pedro, an eminent Portuguese mathematician, was born at Alcacer do Sal in 1492. His attainments raised him to a high rank both as a teacher and as a writer in his own peculiar science. He became preceptor to Don Henry, son of King Emmanuel, and was installed in the mathematical chair at Coimbra. He also continued to publish, till his death in 1577, the following treatises:—*De Arte Navigandi*; *Annotationes in Theorias Planetarum Purbachii*; and *De Crepusculis*. It was in this last work that his device for subdividing the arcs of quadrants and other astronomical instruments was first promulgated. It consisted in describing within the same quadrant 45 concentric circles, and then dividing the outermost of these into 90 equal parts, the next into 89, the next into 88, and so on till the innermost, which is divided into 46. The *nonius*, as the instrument was called, was afterwards improved by others, until, in the hands of Pierre Vernier, it reached its present perfection, and received the

name of the *vernier*. A collection of the works of Nuñez was published at Basle in 1592.

NUNEZ, or KAKUNDY, a river of Western Africa, in Senegambia, flowing westward, and falling into the Atlantic in N. Lat. 10. 40., W. Long. 14. 40. Its banks are thickly wooded, and very unhealthy. Some traffic is carried on in gold, ivory, hides, &c.

NUREMBERG (Germ. *Nürnberg*), a town of Bavaria, in the circle of Middle Franconia, stands on the Pegnitz, an affluent of the Regnitz, 95 miles N. by W. of Munich. It is built on both sides of the river, which is crossed by several bridges, on a sandy but fertile plain, about 1000 feet above the level of the sea; and from whatever side it is viewed, the towers of its churches present a very fine appearance. No other German town retains so much of the appearance and character of the middle ages; indeed, the principal feature of the town is the air of antiquity which pervades it. It is encircled by a high wall, from which rise numerous turrets, said to have formerly been 365, but now about 100 in number. Outside of the wall is a dry ditch, 50 feet deep and 100 broad, the sides of which are lined with masonry. The town is entered by four principal gates, which are flanked by large round watch-towers, no longer necessary for purposes of defence, but adding to the picturesque appearance of the place. The streets are narrow and irregular, lined with antique houses, having in general narrow but highly-ornamented fronts, and pointed gables fronting the street. The ground stories are low, and generally employed as warehouses; but the upper apartments, occupied as dwellings, are often richly adorned with carving and stucco, while many of the larger houses include two or three open courts. There are numerous public squares, of which the chief are—the principal market, in one corner of which is a fountain surmounted by a Gothic obelisk, with statues in stone; St Giles' Square, which contains a statue of Melancthon; and the Goose Market, adorned with a fountain and bronze image. The largest and finest church in Nuremberg is that of St Lawrence a Protestant place of worship, which stands on the south side of the river, and gives its name to that part of the town, as the church of St Sebald does to the other. It was built at the desire of the Emperor Adolphus of Nassau, in the thirteenth century, and has recently been completely restored. It is in the Gothic style, with two elegant towers surmounted by tapering spires. The portal at the west end is most profusely adorned with sculptures, and over it is a fine circular window 30 feet in diameter; while the interior is very rich in stained glass and ancient pictures. Its principal ornament, however, is a tabernacle, or repository for the sacramental wafer, a pyramidal erection of stone, 64 feet high, adorned with most exquisite carving. The church of St Sebald, though inferior to the former, is still one of the finest Gothic buildings in Germany, the west end being in the round style of the tenth century, while the towers, nave, and east end are of a later date, in the pointed style. The bronze shrine of St Sebald, the masterpiece of the celebrated Peter Vischer, who completed it, with the assistance of his sons, in 1519, after thirteen years' labour, is the chief object of interest here. It consists of a rich Gothic canopy supported by slender pillars, having beneath it the oaken coffin of the saint, adorned with silver plates; and although the church is now used for the Lutheran service, this magnificent monument is allowed to retain its place. The Catholic church, or *Frauenkirche*, was founded by the Emperor Charles IV., and completed in 1361, in the best style of German-Gothic architecture. It contains many ancient monuments, and a complicated clock, which shows the movements of the sun and moon. Besides these, there is also a Gothic chapel, dedicated to St Maurice, which is now used as a picture gallery. The town-hall, a building in the Italian style, erected in 1619, contains

Nunez
||
Nurem-
berg.

Nurpoor
||
Nursia.

within it an older portion, built in 1340. The great hall, which is 76 feet long and 28 wide, is adorned with paintings by Albert Dürer; and there is a smaller council-chamber above. Underneath the building there are dismal dungeons and a torture-chamber; and subterranean passages have recently been discovered leading beneath the city to the town ditch. To the north of the town, on a sandstone rock, stands the castle, built in 1030 by the Emperor Conrad II., and presented by the town in 1855 to the king. It is now used as a royal palace; and contains a linden tree, said to have been planted by Queen Kunigunda 700 years ago. Nuremberg has a grammar school, founded by Melancthon, whose statue adorns its front; a public library, with 30,000 volumes; a school of design; polytechnic, industrial, and other schools; a theatre; a general and a military hospital; a deaf-and-dumb asylum; orphan hospital; and other benevolent institutions. There are also several scientific societies. The churchyard of St John, about half a mile to the N.W. of the town, is remarkable as having been the burial-place for several centuries of the aristocracy of Nuremberg. It contains 3500 grave-stones, all regularly numbered, and most of them adorned with the armorial bearings of the dead. Between this and the city gate stand seven stone pillars, with sculptures representing scenes in the passion of our Saviour. Nuremberg is at present the most important manufacturing and commercial town in Bavaria. Cloth, brass, bronze, and steel-ware, wires, needles, musical and mathematical instruments, toys, and black-lead pencils are the principal articles made; and in these an extensive trade is carried on, as this place is the chief mart for goods passing between the north and the south of Europe. It was formerly a much more important city, and in the middle ages rose to a great height in wealth and prosperity. The earliest mention of the town is about the middle of the eleventh century, when it received from Henry III. the privileges of a free market, and the right of coining money and levying toll. From this time it steadily increased in wealth and population, and obtained further privileges from subsequent emperors. In 1219 it was made a free city, independent of any European power; and as such it continued till it was given over by Napoleon in 1806 to the King of Bavaria. The period of its highest prosperity was during the fifteenth and sixteenth centuries, when it was able to furnish 6000 men to the imperial army. But the discovery of the passage to India by the Cape of Good Hope, by directing the commerce with the East into a different channel, led to the decline of Nuremberg as a place of trade; and though it has recently again risen in importance, it has never regained its mediæval prosperity. At the Reformation the inhabitants early embraced the Protestant cause; and in the Thirty Years' War they were on the side of the Swedes, and suffered much in 1632, during the blockade which Gustavus Adolphus endured from the imperial forces under Wallenstein. Nuremberg was the birthplace of many remarkable men, among whom the most distinguished is Albert Dürer the painter, whose house is still to be seen. Pop. (1843) 45,381; (1855) about 50,000.

NURPOOR, a town of British India, in the Baree Doab division of the Punjab, on a small affluent of the Ravee, among the lower mountains of the Himalaya chain; N. Lat. 32. 18, E. Long. 75. 57. A large proportion of the inhabitants are Cashmerians, who are employed in the weaving of shawls. The town has a large and well-supplied bazaar; and derives much importance from its position on the route between India and Cashmere. It was originally governed by a hereditary rajah, but was afterwards seized by the Sikhs. There is a fort of stones and mud, on an eminence 200 feet high, but it is commanded by the higher elevations which surround it. Pop. 6000 or 8000.

NURSIA, an ancient city of the Sabines, situated at

the foot of that lofty group of the Apennine range now known as the Monti della Sibilla. From the nature of its position, in the immediate vicinity of high mountains, the climate of Nursia was somewhat cold. Virgil alludes to it as *Nursia frigida* (*Æn.* vii. 716), and Silius Italicus (viii. 417) does the same. It is mentioned by Livy (xxviii. 45) as furnishing volunteers for the armies of Scipio during the second Punic war, about two centuries before the Christian era. At this period it must have been one of the most important towns of the Sabines, as it is mentioned in the same connection as Reate and Amiternum. Under the Romans it held the rank of a municipal town, and seems to have been somewhat republican in its sympathies; for we find its inhabitants chastised by Octavian for their adherence to the cause of the democratic party. Columella (x. 421) and Pliny (xviii. 13, § 34) allude to the *rapa Nursina*, or Nursian turnips, as having been celebrated in their day; and Martial (xiii. 20) refers to the same circumstance when he speaks of the *pila Nursina*. From its secluded position, this town is not mentioned in the Roman Itineraries. It gave birth, however, to Vespasia Polla, the mother of the Emperor Vespasian; and at a place called Vespasiæ, not many miles from Nursia, the monuments of this distinguished family were to be seen during the time of Suetonius. It is perhaps more celebrated still as the birth-place of the famous Benedict of Nursia, the founder of the first great monastic order in the Christian church. The place had been made an episcopal see at a very early period, and is said to have had St Eutychius for its first bishop. Massive walls are said to be seen still at *Norcia*, resembling those of the Sabine towns of Reate and Amiternum. These ruins form the only traces of this old Etruscan town.

NURTINGEN, a town of Würtemberg, circle of Schwarzwald, on the Neckar, 14 miles S.S.E. of Stuttgart. It contains an old castle, a church, a rich hospital founded in 1480, and several schools. There are also cotton factories, dye-works, and manufactories of musical instruments. Pop. 4550.

NUSSEERABAD, a cantonment of British India, in the district of Ajmeer, North-West Provinces, stands on a large sandy plain, 15 miles S.E. of Ajmeer; N. Lat. 26. 20, E. Lon. 74. 50. It is large, and regularly laid out, with broad streets, and has several tanks and wells. The climate is considered superior to that of any other station in India; but the heat is very great, sometimes in summer rising above 100°. The mean annual temperature is about 76°.

NUTMEG, the kernel of the fruit of *Myristica fragrans*, Houttuyn (Nat. Ord. *Myristicaceæ*), and two or three other species of the same genus. The common nutmeg tree grows from 20 to 25 feet in height, and is very handsome in form and habit. The fruit, which is abundantly produced, resembles the peach in colour, but is rather pear-like in shape. This fruit consists of four parts. The outermost is a thick fleshy pericarp, which has a strong flavour of nutmeg. This portion is not generally used, but is occasionally preserved in syrup as a sweetmeat. The next portion is the curious scarlet mesocarp or arillode, called *mace*. This incloses the endocarp, which is a thin and brittle shell of a shining brown colour, furrowed longitudinally by the pressure of the mace, and within this shell is the *kernel*, or nutmeg. Nutmegs are imported from Penang and other Indian islands. The quantity imported in 1856 was 468,501 lb., of which a considerable quantity was again exported to other countries. Nutmegs are packed in very strong chests, and are usually powdered with lime, to prevent the attack of a weevil-like insect, the *Aræocerus coffeæ*, which is very destructive, often destroying the entire contents of a chest (about 2½ cwt.), of the value of L. 35. Besides the common nutmeg, a sort called the *long*, or *wild nutmeg*, is frequently imported. It is usually inclosed in the shell, and is nearly twice as long as

Nurtingen.
||
Nutmeg.

Nutrition
||
Nuts.

the common nutmeg, but not any thicker. This is the fruit of *Myristica fatua*, Houttuyn. It is brought from the Banda Isles, and is inferior to the common nutmeg. The nutmeg yields, by expression, a solid yellow fat, called *oil of mace*, or *butter of nutmegs*, which is sometimes used in pharmacy. (See OILS.) The duty on nutmegs is one shilling per pound. (T. C. A.)

NUTRITION. See FOOD, and DIETETICS.

NUTS. The term nut is applied to that class of fruits which consist generally of a single kernel inclosed in a hard shell. Botanically speaking, they are one-celled fruits with hardened pericarps, more or less enveloped in a cupule or cup, formed by the aggregation of the bracts. Several nuts are of considerable importance, in consequence of their sweet edible kernels, and some from their abundant oil.

The common *Hazel-nut* of the shops, or the *small nut* of our import tariff, is the fruit of the hazel (*Corylus avellana*, W.) The hazel-nut is now found generally throughout the temperate parts of Europe and in many parts of Asia. In Spain, Sicily, and some parts of Turkey, it is very extensively cultivated, and forms an important article of trade. The import of hazel-nuts to this country alone is immense. In 1857 it was about 224,486 bushels, of which the chief part came from Spain, and the remainder from Sicily, Smyrna, and Constantinople. From Spain we receive two principal kinds, but they appear to differ only in the circumstance that the so-called *Barcelona* nut is kiln-dried, whereas the Black Spanish is the fresh ripe nut. The latter is only sent at the commencement of the season, as it will not keep long. They are usually sent in bags of two bushels each; but it not unfrequently happens that they are imported in bulk, especially from Smyrna, whence we receive the small red nut (*Corylus Colurna*, Willd.) Besides its extensive use as an edible fruit, the hazel-nut yields an oil which is much valued by artists in oil-colours and by watch-makers. (See OILS.) The filbert is extensively cultivated in England, particularly in Kent; and the common hazel is one of the commonest of our coppice shrubs. The *Walnut* is the fruit of *Juglans regia*, Linn. (Nat. Ord. *Juglandaceæ*), and is found in the northern parts of Asia. It seems probable that the nuts mentioned in Genesis xliii. 11, were walnuts, as Pliny says the native country of the nut is Pontus, and vast quantities are still gathered in the neighbourhood of Trebizond. He mentions two kinds, both of which were occasionally eaten roasted, viz., the *Abellina* (*C. avellana*, W.), so named from Abellinum in Campania; and another kind, which is supposed to have been the filbert (*C. tubulosa*, W.) The walnut tree is now cultivated generally throughout Europe, and is as much valued for the fine timber it produces as for its edible nuts. In this country the young green nuts, before the shells become hard, are gathered in considerable quantities and made into a favourite pickle. The nuts are imported from Germany, Italy, France, and Spain, and sometimes from Turkey: 57,000 bushels were imported from these places in 1857. They are only used in this country as an eatable fruit; but in Cashmere they are pressed for oil in great quantities. The *Hog-nut* (*Juglans porcina*, Michaux), and the *Black walnut* (*Juglans nigra*, Linn.), natives of Canada, are occasionally brought in small quantities from that country, and are sometimes seen in our fruiterers' shops, but are inferior to the common walnut. Two other nuts, closely allied to the walnut in the same natural order, are the *Hickory-nut* (*Carya alba*, Nuttall), with which are often mixed the nuts of *C. sulcata*, Nutt., now frequently brought from the United States. These, however, are so much alike that they are not ordinarily recognised as distinct from each other. They are smaller than the walnut, have smooth hard shells of a light colour, resembling common deal-wood, are marked by longitudinal ridges, and do not split into two shells. The *Peccan-nut* (*Carya oliviformis*, Nuttall), usually imported from New Orleans, is nearly of the shape and size of the olive, but somewhat longer and thinner. The shell of this favourite nut is very thin and smooth, and the kernel plump and large. The quantity of hickory and peccan nuts annually imported is small, probably not exceeding 800 bushels; but it cannot be ascertained with certainty, as the greater part received is in the form of presents. They are, however, beginning to be in demand in our markets. The *Chestnut* is produced by a large tree (*Castanea vesca*, Gaertner), Nat. Ord. *Corylaceæ*. The tree takes its name from Castana in Thessaly, but is so commonly distributed over Europe that it is probably indigenous to most of the southern countries of that continent. It is very abundant in Spain, whence we receive the greater part of the chestnuts brought to this country. It was well known to the Romans; and Pliny speaks of eighteen varieties of this fruit. He says it was called by the Greeks *Dios balanon*, or

Nux
Vomica.

"Jove's acorn," and Sardian acorn, from its having been first introduced by the people called Sardes. In his day the choice sorts were roasted and eaten, and the inferior ones used for feeding pigs. Of late, limited quantities of small sweet chestnuts have been imported from the United States, which are probably the fruit of *Castanea vesca*, naturalized in America. The quantity of chestnuts imported from Spain and other parts in 1857 was 84,000 bushels. The *Brazil-nut*, or *Juvia*, is the fruit of one of the largest trees of the Brazilian forests, the *Bertholletia excelsa*, Humboldt and Bonpland (Nat. Ord. *Lecythidaceæ*). This nut, which is also called *Para-nut* and *Castanha-nut*, is at first inclosed in an outer apple-shaped shell as large as a moderate-sized melon. This usually contains about twenty of the nuts, which average an inch and a half in length, and are thick and triangular in the middle, but sharp at each end, with a rough greyish-brown shell. The kernel is very sweet and oily. They are imported chiefly from the ports of Para and Maranhão, generally in bulk. The import for 1857 was 27,000 bushels. The *Sapucaia-nut*, another Brazilian fruit, is also seen occasionally in our fruit shops. It is produced by a large tree of the same natural order as the *Bertholletia*, called *Lecythis ollaria*, or "Cannon-ball tree." Its specific name is taken from the large urn-shaped capsules, called "monkey-pots" by the inhabitants, which contain the nuts. The *Sapucaia-nut* has a sweet flavour, resembling the almond, and if better known would be highly appreciated. They are, however, scarce, as the monkeys and other wild animals are said to be particularly fond of them. This nut, which is of a rich amber-brown, is not unlike the Brazil-nut, but it has a smooth shell furrowed with deep longitudinal wrinkles. The *Sapucaia-nut* has hitherto only been imported into Liverpool; and the whole quantity is not more than forty or fifty bushels per annum. The *Pistachio-nut* is the fruit of *Pistacia vera*, Linn. (Nat. Ord. *Anacardiaceæ*). It is a native of Syria. Although a remarkably delicious nut, and much prized by the Greeks and other eastern nations, it is not well known in this country. It is not so large as a hazel-nut, but is rather longer and much thinner, and the shell is covered with a somewhat wrinkled skin. The quantity imported is very small and uncertain. The small nut of *Pistacia lentiscus*, Linn., not larger than a cherry-stone, is also occasionally imported from Smyrna, Constantinople, and Greece. The *Cashew-nut* belongs to the same natural order as the *Pistachio*. It is the fruit of a small tree, the *Anacardium occidentale*, a few bushels of which are occasionally sent from the West Indies, where it is a native. The *Cajou* or *Cashew nut* is remarkable in consequence of the enlargement of the receptacle or peduncle after the flower falls. This receptacle, on the top of which the nut grows, becomes as large as a good-sized pear, and is sweet and agreeable to the taste. The *Souari* or *Surahwa nut*, called also the "Butter-nut of Demerary," and by our fruiterers the "Suwarrow-nut," is the fruit of *Caryocarp butyrosam*, Willd. (Nat. Ord. *Rhizophoraceæ*),—the *Pêkea butyræa* of Aublet, a native of the forests of Guyana, growing 80 feet in height. This is perhaps the finest of all the fruits called nuts. The kernel is large, soft, and even sweeter than the almond, which it somewhat resembles in taste. The few that are imported come from Demerary, and are about the size of an egg, somewhat kidney-shaped, of a rich reddish-brown colour, and covered with large rounded tubercles. The *Cocoa-nut* is the fruit of *Cocos nucifera* (Nat. Ord. *Palmaceæ*). This nut is, when ripe, inclosed in a large fibrous husky shell, which yields the vegetable fibre called *coir*. The kernel forms an inner coating to the hard shell, about three-quarters of an inch thick, inclosing at first a sweet limpid liquid, called the milk, which afterwards becomes the albumen of the seed. It is the inner fleshy portion of the kernel which is eaten. In the tropics it is universally regarded as a very wholesome and nutritious fruit, and yields a large quantity of oil. (See OILS.) Cocoa-nuts are imported from the West Indies, and sometimes from Western Africa. About a million and a half are received annually. *Ground-nuts* are the fruits of *Arachis hypogæa* Linn. (Nat. Ord. *Leguminosæ*). They are roundish, irregular-shaped pods, improperly called nuts, of a straw colour, covered with small square depressions, arranged with considerable regularity. They contain two or three reddish-brown seeds, which have the flavour of the gray field-pea. They are sometimes eaten when roasted, but are chiefly used for expressing oils. (See OILS.) They are sometimes imported in large quantities from Africa and the West Indies. It is said to be a native of South America, but there is reason to believe it came originally from Africa. (T. C. A.)

NUX VOMICA, the seeds of a moderate-sized tree, *Strychnos Nux-Vomica*, Linn. (Nat. Ord. *Loganiaceæ*, Div. *Strychnææ*), a native of the coast of Coromandel. The nux vomica, or poison-nut, has been known for a long time, and is supposed to have been made known to Europe by the Arabian physicians; but one or two other seeds have evi-

Nyassi
||
Nyiregy-
haza.

dently been confounded with it. The pulpy fruit which incloses the seed is about the size of an orange, with a thin brittle shell, of a brilliant orange colour; and, from the fact that the pulp is eaten by birds, would seem to be innocuous. The fruit contains many seeds, imbedded in a white gelatinous pulp. These seeds are about three-fourths of an inch in diameter, quite circular, slightly convex on one side, and depressed on the other; of a peculiar silky appearance, and of a light-drab colour, not unlike silk-covered buttons. They are very hard and horny, and consist chiefly of dark greenish-gray albumen, in which their intensely poisonous quality resides. The deadly powers of this seed are due to the presence of the alkaloid called strychnia or strychnine, a salt consisting of $C_{44}H_{24}N_2O_8$; but it contains another poisonous alkaloid called brucine, of nearly similar composition— $C_{44}H_{25}N_2O_7$. It was discovered in 1818 by Pelletier and Caventou, and it was afterwards proved by M. Magendie and by Dr Fouquier that the salt possessed a remarkable specific action upon the spinal marrow without particularly affecting the brain. It has consequently been found very serviceable in certain spinal diseases, but its administration requires excessive care. Almost every part of the tree, except the pulp of the fruit, partakes of the intense bitter of the seed. The poisonous bark introduced into Europe as angostura bark did not come from South America, but from India, and proves to be that of the *S. nux-vomica*. The wood is very hard, and is used as a useful kind of timber. The imports of nux vomica were only 550 lb. in 1840; but in 1857 it was over 1000 bags, or about 250 cwt. The use to which this large quantity of so powerful a poison is applied is by no means clear. Much is employed for the destruction of rats and other noxious animals, but not sufficient to account for so great an increase. It is free of duty, and is almost always imported from Bombay in small bags of about 28 lb. each, and is worth from 6s. to 8s. per cwt. (T. C. A.)

NYASSI, or *The Sea*, a lake in the interior of equatorial Africa, has been known by report to Europeans for about three centuries, but has never yet been reached or explored by them. The latitude of its centre is about 10° S., and it is believed to extend from S.E. to N.W. between E. Long. 30. and 35. It is known by various names, and appears to be the same as the lake called Maravi on old maps. The great rivers Nile, Zaire, and Zambesi have been supposed to take their source from this lake, but the truth of the statement is more than doubtful.

NYIREGYHAZA, a market-town of Upper Hungary, in the county of Szabolcs, 29 miles N. of Debreczin. It has a Greek, a Roman Catholic, and two Protestant churches; a Protestant school; saltpetre-works; and mineral springs. A yearly market of considerable importance is held here. Pop. (1851) 13,826, mostly Protestants.

NYKÖPING, a seaport-town of Sweden, capital of a ^{Nyköping.} ~~län~~ of the same name, stands on an inlet of the Baltic, 54 miles S.W. of Stockholm. It is regularly built, and contains a new and an old castle, several courts and public offices, three churches, an hospital, and manufactories of linen, cotton, and woollen stuffs, hosiery, tobacco, needles, &c. Pop. 3486. The län is bounded on the N. by Lake Mälär, which separates it from Upsala and Westeras, E. by Stockholm and the Baltic, S. by Linköping, and W. by Örebro. Area 2497 square miles. Many valuable minerals, such as iron, copper, lead, &c., are obtained here: the higher regions are well wooded, and the plains fertile and well cultivated. The bays on the Baltic coast facilitate the exportation of metals, timber, corn, and cattle. Pop. (1850) 120,113.

NYMPHS (Gr. *νύμφαι*, Lat. *nymphæ*), in Greek and Roman mythology, a class of inferior female deities of almost infinite number, who were held to preside over all parts of the earth. They were commonly represented as beautiful young women, and generally in the train of some of the greater divinities, such as Neptune, Juno, Diana, or Pan. In most parts of Greece and Italy they were worshipped with offerings of kids, lambs, milk, or honey, but never of wine. In the latter country they were sometimes honoured with special temples or chapels. The interest they took in men and human affairs was believed to be entirely of a kindly and beneficent nature. They presided alike over the dry land and the watery element. In the former class the most important were the mountain nymphs, the *Oreades* or *Orodesmiades*, who also took local names from the special hills which they haunted, such as *Cithæronides*, &c.; the nymphs of trees, the *Dryades* and *Hamadryades*, whose life was commensurate with that of the forest tree in which they had their abode; and the nymphs of valleys and groves, the *Napææ*, &c. Of the water-nymphs the most important were the *Oceanides*, the daughters of Oceanus and Tethys, said to be 3000 in number. After them may be named the *Nereids*, the daughters of Nereus and Doris, fifty in number, of whom the most famous were Amphitrite, the wife of Neptune; Thetis, the mother of Achilles; Galatea, &c. Their favourite haunt was the Ægean Sea, and they were held in high honour throughout Greece, especially at Corinth. The river-nymphs, the *Potameides*, were worshipped under local names, derived from the special rivers over which they presided; such as *Acheloides*, from the Achelous; *Pactolides*, from the Pactolus, &c. The *Naiades*, or nymphs of the fresh water, were known as *Limnades* and *Crenææ*, or *Pegææ*, according as they inhabited lakes or springs. Even the waters of Hades had their presiding nymphs, the *Avernales*, many of whom were believed to be endowed with prophetic power, and to communicate that gift to their favourites among men.

O.

O, the fifteenth letter and the fourth vowel of the English alphabet, occupies a position in point of sound between the vowels *a* and *u*. The shape of the letter seems to have originated in the circular form assumed by the lips in pronouncing it; yet in the hieroglyphical characters, and even in the ancient Greek alphabet, it appears to have been taken from the shape of the eye. In English *O* has a long sound, as in *bone*, *moan*, *broke*, *roll*, which is usually denoted in a word or syllable by a final *e*, as in *bone*, *lonely*, or by a servile *a* as in *moan*, *roaming*. It has also a short sound as in *hot*, *long*, and a soft sound like the Italian *u* and the French *ou*, as in *move*, which is shortened in words ending in a close articulation, and represented by *oo* as in *look*, *root*. The vowel *o* is convertible with a variety of vowels and of vowel combinations, in English, as well as in other languages; e.g., what is *o* to the eye is *u* to the ear in the words *son*, *none*, *done*, *won*. The English *o* in the words *one*, *two*, *gone* becomes *a* in Scotch as *ane*, *twa*, *gane*; and *o* interchanges with *ea* in *cleave*, *clove*; *heat*, *hot*, &c. *O* was used as a numeral by the ancients to represent 11, and with a dash over it (*Ö*) to denote 11,000. Among the Irish *O* prefixed to proper names, like *Fitz* in England and *Mac* in Scotland, signifies *son of*, as *O'Neal*, the *son of Neal*; and was originally employed as a character of family dignity. *O*, a circle, or *CO* is called by the Italians *circolo*, and is used by them to express *tempo perfetto* in music, or what we call triple time. (For the use of *Ö* in abbreviations, see ABBREVIATIONS.) *O* is often employed as an interjection to express a wish, admiration, pity, surprise, &c.; but when strong emotion is to be conveyed, the exclamation is written *Oh*!

OAK. See PLANTING, TIMBER, and SHIP-BUILDING.

OAKHAM, or **OKEHAM**, a market-town of England, capital of the county of Rutland, stands in the fertile vale of Catmore, 17 miles E. by N. of Leicester, and 85 N.N.W. of London. It is pretty well built; and contains an old castle supposed to have been built in the reign of Henry II., and now used as a county-hall; an ancient parish church, with a lofty spire; Presbyterian, Independent, Wesleyan, and Baptist places of worship; national schools; and a free grammar school, founded in 1584, with an hospital for old men attached to it. The chief manufacture is that of silk shag for hats. Oakham is not commercially of much importance; and, though some traffic in coals is carried on, it depends principally on its retail trade in articles of home use. There is a canal between this place and Melton-Mowbray. Several yearly fairs for cattle and sheep are held here. Pop. (1851) 2800.

OASES was the name given by ancient writers to the verdant spots that occur at intervals in the midst of the waste sands of Africa, and is said to be derived from the Coptic word *ouah*, a resting-place. The foundation of an oasis is a hollow stratum of sandstone or clay, which retains the moisture that flows into it, and which is encircled by a rim of the limestone that forms the bed of the surrounding desert. On this basis springs up in green luxuriance an orchard of date, fruit, and other trees, interspersed with wheat and millet. These oases, as the etymology given above implies, seem to have been originally used merely as halting-places for the Egyptian and Ethiopian traders in their journey through the desert. It was not until the Persian conquest of Egypt that they became permanent settlements. They were afterwards garrisoned by the Greeks and Romans in succession; and at a still later period they became a place of refuge, first to persecuted Christians, and then to heretics. Their number was great.

Herodotus likens them to a chain stretching from E. to W. through the Libyan desert. But the most celebrated were four, called respectively Oasis Magna, Oasis Trinytheos, Oasis Minor, and Ammonium. The Oasis Magna (the modern *El-Khargeh*) is about 90 miles W. from the banks of the Nile, and is 80 miles in length, and from 8 to 10 in breadth. It was a district of great importance in ancient times. Herodotus called it the "City Oasis;" and Josephus called it "The Oasis" *par excellence*. In pagan times it was the site of a temple 468 feet long, and dedicated to Amün-Ra; and after the commencement of the Christian era it was crowded with churches and monasteries. The Oasis Trinytheos (the modern *El-Bacharieh*) was situated N. from the Oasis Magna, and W. from the city of Hermopolis Magna. There is no evidence that it was ever a permanent settlement of the Egyptians, the Persians, or the Greeks. The most ancient architectural remains are Roman. The fact, however, that several Artesian wells have been recently discovered there, and that the construction of these was unknown to the nations above mentioned, seems to indicate that the Oasis Trinytheos was visited at an early period by some people who had imported the art of making artificial springs from the eastern countries of Asia. The Oasis Minor (the modern *El-Dakkeh*) was situated nearly N. from the Oasis Magna, and W. from the city of Oxyrynchus. The ruins of a temple and several tombs show that it was a station of the Greeks. It was also under the dominion of the Romans, and was then famous for its wheat. Ammonium (the modern *El-Siwah*) was situated N.W. from the Oasis Minor. Though not more than 6 miles in length and 3 in breadth, it was at one time the most famous of all the oases. Its soil produced salt in great abundance and of the finest quality, and at the same time was well watered and fruitful. There also was the celebrated "Fountain of the Sun" which Herodotus saw in the fifth century B.C. There especially was the temple of Jupiter Ammon, which Alexander the Great visited in 331 B.C., and which was built of stone, of a blue and green colour, and covered with hieroglyphics. The fountain is still seen springing up in a grove of dates; and the walls of the temple, retaining their bright colouring, are still seen in ruins near the village of Gharmy.

The term *oasis* has in modern times come to signify any fertile tract in the midst of a desert.

OATES, **TIRUS**, the infamous fabricator of the "Popish Plot," was born about 1619. From the very first he was an apostate and a deceiver. He left the Anabaptists, among whom he had been trained, and after studying at Cambridge, accepted a benefice in the Church of England. With this position his life and opinions were soon found to be glaringly inconsistent; and he entered a Jesuit college in France. Even there his conduct was too unprincipled to be endured; and in 1677 he found himself obliged to take up the profession of a scheming vagabond. It was then that Oates, animated probably by the hope of gain and the love of low intrigue, resolved to take advantage of the alarm into which the English nation had been thrown on account of the suspected Popish inclinations of Charles II., the avowed Popish opinions of the Duke of York, and the growing confidence of the Papists in general. He patched up a chimerical story, and communicated it to the government at London as a plot which had been formed by the Roman Catholics. The capital, he said, was to be set on fire, the citizens massacred, the king assassinated, Ireland invaded by a French army, and certain Papists whom he named placed in the high offices of the state. This fabri-

Oates.

Oaths.

cation realizing the apprehensions in the public mind, and seeming to be corroborated by certain events, gained universal credence. The government were at their wits' end; all London was instantly on the alert for the expected attack; and the people, hurried on by the blind instincts of hatred to their foes and gratitude to their supposed saviour, rushed into an extreme course of action. Oates was raised to the summit of popularity and power; a pension of L.900 a year was conferred upon him; nothing less magnificent than a suite of apartments in Whitehall Palace was thought worthy of lodging his precious person; and whenever he appeared in public he was greeted by the unbanned populace. The fresh fictions which he continued to invent regarding the plot were also received without hesitation. With the aid of certain worthless associates, he procured the conviction of many innocent Roman Catholics, and was the main cause of a series of judicial murders which extended over the space of two years. By that time, however, the nation was opening its eyes upon the monstrous system of deceit by which it had been duped, and a storm of retribution was gathering against the head of the arch offender. On the accession of James II. in 1685, he was tried before the Court of King's Bench, was convicted of perjury, and was sentenced to be first pilloried and whipt at the cart's tail, and then to be imprisoned for life. The former part of the punishment was executed with a severity which was evidently intended to kill him. The latter part was broken off by the accession of William III., and the simultaneous re-action in the state of public feeling. The trial of Oates was then declared by Parliament to have been illegal; his crimes were pardoned by the king; and he was allowed to skulk away into obscurity with a pension of L.300 a-year. He died in 1705. (For the particulars of the "Popish Plot," see BRITAIN. See also Lord Macaulay's *History of England*.)

OATHS are solemn declarations made, with an appeal to God or to some superior being, for the truth of what is affirmed, or for the honesty of what is promised. It is always to be presumed, in the taking of an oath, that the person imposing it believes that the swearer expects the superior being whom he calls to witness will visit him with punishment in the event of his violating that oath. On no other supposition can an oath be conceived of any value or significance. The person making the oath may or may not fear the evil consequences of perjury; but the individual imposing the oath is supposed to believe that the swearer is apprehensive of those consequences. Oaths are *assertory*, or those by which something is affirmed as true; and *promissory*, or those by which something is promised to be done. Oaths are again either voluntary or compulsory.

Jewish oaths.

It would appear, from all that can be gathered on the subject, that the practice of using oaths on certain important occasions has been observed in all nations where any definite idea of a superior being has prevailed. This practice is found as early as the days of Abraham, who charges his servant: "Put, I pray thee, thy hand under my thigh; and I will make thee swear by the Lord, the God of heaven and the God of earth, that," &c. (Gen. xxiv. 2, 3, 37). This oath was private rather than judicial or national. Instances of public or national oaths, in which an entire kingdom or a large body of people were involved, are to be found in Judges xxi.; also in 1 Kings-xviii. 10; and the first example of a strictly judicial oath is to be found in Levit. vi. 3-5. This custom of oath-making, which had been in use amongst the Jews from the earliest times, was sanctioned by Moses, and employed by him in connection with his code of laws. Other beings besides God were sometimes invoked in taking an oath, among the Hebrews and certain other nations of the East; as the soul (2 Kings ii. 2; 1 Sam. xx. 3, &c.); the head or life of a

king (Gen. xlii. 15). The most solemn oath among the Persians, according to Hanway, is, "By the king's head;" and Aben Ezra informs us that this oath was common in Egypt in his time (A.D. 1170) among the khaliphs. Sometimes the oath-taker swore by some precious part of his own body, as the head (Matt. v. 36); by the earth, the heaven, and the sun (Matt. v. 34, 35); by angels (Josephus, *De Bell. Jud.* ii. 16, 4); by the temple (Matt. xxiii. 16); and by Jerusalem (Matt. v. 35; compare *Lightfoot*, p. 281). The levity of the Jewish nation with regard to oaths became notorious; and while we find some of their doctors sharply reproving this vice (Othon. *Lex.*, p. 351; Philo, ii. 194), it is nevertheless notorious that the rabbinical writers, by their nice distinctions, subtle casuistry, and perverse ingenuity on the subject of swearing, did much in effect to countenance open falsehood, and lessen the enormities of perjury and profanation. The heathen satirists poisoned their shafts against the Jew with the blasphemous perjury of that race (Martial, xi. 9); and when we come down to Christian times, we find a growing disposition to discountenance a practice which had been prostituted to the worst of purposes. Some contend that the language of Christ respecting oaths (Matt. v. 34-37) is absolutely prohibitory of that practice; while others, with perhaps greater justice, suppose that his words apply to profane and wanton swearing, rather than to solemn and judicial oaths. Not a few of the early fathers held oaths to be unchristian; and some modern sects, such as the Quakers, &c., decline, on Scriptural grounds, to take oaths in courts of law.

Oaths.

Among the Greeks, oaths seem to have been taken both between individuals and nations, on certain solemn occasions, from a very early period. When the fate of the Trojan war was to be decided by single combat, the agreement was ratified by oath. (*Iliad*, iii. 276.) A similar practice was observed in other treaties and alliances, as appears from Herod. i. 69, 74, 146, 165; Thucyd. v. 47. As is abundantly obvious from their writers, the Greeks held in great reverence the sanctity of oaths. Illustrations of this are to be found especially in Homer, Æschylus, Pindar, Euripides, and Sophocles. The ingenious prevarication and mental reservation of a Jew or a Jesuit was precisely what Homer's great hero, in his noble heathenish indignation, hated "like the gates of hell" (*Iliad*, ix. 313). The story of Glaucus the Spartan, who was annihilated with his whole family for simply entertaining the question as to whether or not he should fulfil an oath, affords a good illustration of Greek feeling upon the crime of perjury. (See Herodotus, vi. 86; Juvenal, xiii. 202.) It is but too well known, however, that, with the decay of everything great and noble among the Grecian states, the crime of perjury became an every-day occurrence; and a Greek became among the Romans only another name for a liar. Each nation or people swore by its own deity or hero: as the Thebans by Hercules, the Lacedæmonians by Castor and Pollux, and the Corinthians by Neptune. An oath was often suggested by office, character, place, or sex. Thus Iphigeneia the priestess swore by Artemis; Antilochus, in talking of horses, is told to swear by Poseidon, the equestrian deity; Achilles swears by his sceptre; Telemachus by his father's sorrows; Demosthenes by the heroes of Marathon; and Pythagoras by the number Four. If the men found it necessary to swear by Hercules and Apollo, the women felt called upon to give weight or ornament to their words by invoking Aphrodite and Demeter. Citizenship was ratified by oath in Athens, and public functionaries were sworn in to their office. It is supposed that the oaths occasionally taken by witnesses in judicial proceedings were, for the most part, voluntary among the Greeks. Oaths with the Greeks were frequently accompanied by sacrifice and libation, and the swearer placed his hands upon the victim,

Oaths. the altar, or some other sacred thing, while he was taking the oath. (Livy, xxxi. 50.)

Roman oaths. Among the Romans, magistrates and other dignitaries had to come under an oath, in entering upon the public service, to protect and observe the laws. All Roman soldiers, on their enlistment for a campaign, had to take the military oath (*sacramentum*), binding themselves to be faithful to the commands of their superior officers. (Livy, xxii. 38.) In transactions with other nations, oaths were taken in the name of the Roman republic. Livy has recorded (i. 24) the most ancient form of this kind of oath, in a treaty struck between the Romans and the Albans. Jupiter was invoked, while the priest struck the victim with a flint-stone (*lapis silex*); and from the important part played by this instrument in oath-taking, the god himself came to be called Jupiter Lapis. During the latter years of the republic, the early reverence for international oaths became well nigh forgotten; and in perjury, both individual and national, the Roman came to rival the Jew and the Greek. The remarks already made respecting the conversational oaths of the Greeks apply pretty correctly to those of the Romans: Hercules, Pollux, Jove, and Bacchus were the favourites of the men; while women, lovers, and exquisites garnished their soft speech by appeals to Juno and Venus. Examples of this practice are endless among the classical writers. In Roman judicial proceedings, oaths were occasionally required from the plaintiff or defendant, or both. The oath of calumny (*jusjurandum calumnie*) was taken by the plaintiff in solemn declaration that there was no malice or dishonesty in his suit. It does not seem to have been always necessary to examine prisoners on oath in civil cases; but in the criminal proceedings of the *judicia publica*, oaths appear to have been administered. (Cicero, *Pro Q. Rosc. Com.* c. 15; Noodt, *Op. Omn.* ii. 479; Digest *De Testibus*.)

English oaths. As a general rule, all testimony in English judicial proceedings requires to be given by oath. This custom is said to have been introduced into England by the Saxons A.D. 600. Only those can be sworn as witnesses, however, who will profess their belief in the existence of Deity, in a future state of rewards and punishments, and that perjury will be punished by God. A Jew, a Mohammedan, or a Hindu may be sworn as witnesses by the oath which they severally consider binding. All other persons, such as professed atheists, &c., cannot be admitted to give evidence on oath in judicial proceedings. Young children, imbeciles, &c.; are also incompetent, from deficient intelligence. Quakers and others, who object to taking judicial oaths on Scriptural grounds, are allowed to give their evidence on affirmation, both in civil and criminal proceedings. A peer or lord of Parliament, when a dependant in Chancery, is required to give his answer to a bill upon honour only; and the members of a corporation give in their answer under the seal of their body. Oaths are also required by English law on admission to offices of public trust, as the oath of princes to rule constitutionally, the oath of supremacy, the oath of allegiance, and the oath of office. All who hold offices of any kind under the government, as members of the House of Commons, ecclesiastics, members of colleges, schoolmasters, serjeants-at-law, councillors, attorneys, &c., are required by statute to take the oaths of allegiance, &c. The oath of supremacy was first administered to British subjects (26 Hen. VIII.) in 1535; that of allegiance was framed (3 James I.) in 1605; and the oath of abjuration (13 Will. III.) in 1701. A solemn affirmation or declaration may be substituted for an oath in certain cases by the Lords of the Treasury, according to the Act 5 and 6 William IV., c. 62. (See Knight's *Political Cyclopædia*, vol. iii., p. 436.) The principal sanctions against mendacity in a witness are—(1.) The legal punishment incidental to a conviction of false swear-

ing; (2.) The influence of public opinion; (3.) The dread of future punishment from the Deity. Bentham, in his famous attack upon the taking of oaths in his *Rationale of Evidence*, denies that the third of those considerations has the force of a sanction at all, and maintains that the first and second alone have influence. But it must be obvious to every one, that while the third sanction may not be so universal in its influence as the first and second, it may be, and in point of fact is, in the case of not a few, regarded as a consideration of infinitely greater weight than any other whatever. And, as was said already, it is the opinion of the person who takes the oath that gives it value in the eyes of the person administering or imposing it. Nothing can be more obvious, however, than the very great abuses to which the practice of oath-taking is liable. So long as the moral and religious sense of a nation is sound and pure, its public or private oaths will carry with them a becoming awe and reverence; but no sooner does the national morality begin to decline than perjury becomes an every-day occurrence, and men swear to anything that suits their interest or pleases their caprice. Such, at least, is the lesson taught us by the history of the Jew, of the Greek, and of the Roman. (See Ugolino's *Thesaurus Antiq. Sacr.*, vol. 26; Grotius, *De Jure*, &c., lib. ii., c. 13; Tyler's *Oaths, their Origin, Nature, and History*; the *Cyclopædia of Political Knowledge*; and Smith's *Dict. of Antiquities*.)

OAXACA. See MEXICO.

OBADIAH, the fourth of the minor prophets according to the Hebrew, the fifth according to the Greek, and the eighth according to the chronological arrangement, is supposed to have prophesied about the year B.C. 599. (Jahn's *Introd.*) We possess but a small fragment of his prophecies, and it is impossible to determine anything with certainty respecting himself or his history. Several persons of this name occur about the same period, one of whom presided at the restoration of the temple in the reign of Josiah, B.C. 624, and is considered by many to have been the author of the prophecy. Another, who was governor of the house of Ahab, was regarded by the ancient Jews as the author of the book; an opinion followed by Jerome (Hieron. *Comm. in Abdiam*; Sixtus Senens. *Bib. Sanct.*). Others place the author in the reign of Ahaz, B.C. 728-699; while some think him to have been a contemporary of Hosea, who prophesied B.C. 722. Jahn maintains, from the warnings to the Edomites, ver. 12-14, that Obadiah prophesied before the destruction of Jerusalem by Nebuchadnezzar; while De Wette infers from ver. 20, that the composition of the book must be placed after the destruction of that city. From a comparison of Obad. ver. 1-4 with Jer. xlix. 14-16; Obad. ver. 6 with Jer. xlix. 9, 10; and Obad. ver. 8 with Jer. xlix. 7, it is evident that one of these prophets had read the other's work. That Jeremiah was the original writer has been maintained by Bertholdt, Credner, De Wette, and others. (See Eichhorn's *Introd.*, sec. 512; Rosenmüller's *Scholia*; and Jäger, *Ueb. die Zeit Obadjah*.) His prophecies are directed against the Edomites, and in this respect correspond with Amos i. 11, Jer. xlix. 22, Ezek. xxv. 12-14, and Ps. cxxxvii. 7; but he consoles the Jews with a promise of restoration from their captivity—a prophecy which was fulfilled in the time of the Maccabees, under John Hyrcanus, B.C. 125. The language of Obadiah is pure, but he is too fond of the interrogatory form of expression; his sentiments are noble, and his figures bold and striking. (In addition to the works already specified, the reader may consult Leusden's *Obadiah*; Pfeiffer, *Comm. in Obad.*; Schröer, *Der Prophet Obad.*, &c.; Venema, *Leett. in Obad.*, with the additions of Verschuier and Lohze; Kohler, *Anmerk.*; Schnurrer's *Dissert. Philol.*; Henderwerth, *Obadjæ Prophetæ Oraculum in Idumæas*.)

OBAN, a parliamentary burgh and seaport of Scotland, Argyllshire, 20 miles N.W. of Inverary, and 6 ½

Oaxaca
||
Oban.

Obe
||
Oberlin.

N.W. of Glasgow. It is built in the form of a crescent, round the shore of a bay of the same name, and has an extensive coasting trade with the Clyde, as it is the chief seaport and market-town for a large extent of country. It contains places of worship belonging to the Established, the Free, the United Presbyterian, the Scottish Episcopal, and the Independent churches; several schools, a library, reading-room, savings-bank, and custom-house. The harbour is deep and safe, being sheltered by the island of Kerrera; and the inhabitants are extensively engaged in fishing. Steamers ply regularly between this town and Glasgow; and during the summer it is a great resort for tourists, who make this their starting-place for the various parts of the Western Highlands. The Bay of Oban is surrounded by steep cliffs, on which stand the ruins of Dunolly Castle; while about three miles to the north of the town are the remains of that of Dunstaffnage. Oban unites with Ayr and other burghs in returning a member to Parliament. Pop. (1851) 1742.

OBE, OBI, or OBY, a river of Siberia, rises in the Altai Mountains, where it is formed by the union of two main streams, the Katunga and the Biya. It flows in an irregular course, but generally towards the N.W., till it joins the Irtysh from the south. It then turns northward, and flows in that direction, frequently dividing itself into two streams, which flow separately for long distances, and then unite again. It falls into the Gulf of Obe by three branches, the largest and deepest of which is that which lies to the east. Its whole length is estimated at 2000 miles. The principal affluents of the Obe are the Irtysh, which is longer than the branch which retains the name of Obe, the Tom, the Choolyn, and the Ket; while the Irtysh receives from the west the Tobol and the Iskim. Both the Irtysh and the Obe abound in fish, which might be made a valuable article of export. The country drained by the Obe and its tributaries is calculated to have an area of 1,370,000 square miles. The Gulf of Obe, which derives its name from the above river, is an inlet of the Arctic Ocean, between 70 and 80 miles in breadth, and upwards of 400 in length. It lies between N. Lat. 67. 30. and 72. 30.; E. Long. 72. and 77.

OBELISK, a truncated, quadrangular, and slender pyramid, raised as an ornament, and frequently charged with inscriptions or hieroglyphics. Obelisks appear to have been of very great antiquity, and first raised to transmit to posterity certain precepts, which were cut in hieroglyphical characters; but they were afterwards used to immortalize the great actions of heroes and the memory of persons who were beloved. The first obelisk mentioned in history was that of Remeses, King of Egypt, which was forty cubits high. Ptolemy Philadelphus, another of fifty-five cubits; and Ptolemy Philadelphus, another of eighty-eight cubits, in memory of Arsinoë. Augustus erected one at Rome, transported from Egypt, in the Campus Martius, which served to mark the hours on a horizontal dial drawn upon the pavement. They were called by the Egyptian priests the "fingers of the sun," because they were made in Egypt to serve also as styles or gnomons for marking the hours on the ground. The Arabs still call them "Pharaoh's needles." (See the elaborate work of Zoëga, *De Origine et Usa Obeliscorum*, illustrated with very beautiful and accurate plates; Sir G. Wilkinson's *Ancient Egyptians*; and articles ARCHITECTURE and EGYPT.)

OBERLIN, JEAN FREDERIC, a celebrated philanthropic pastor, was the son of a teacher, and was born at Strasburg on the 1st August 1740. Under the religious instructions of his mother, and of a devout Lutheran preacher named Dr Lorentz, he imbibed that spirit of pious zeal which determined his future career. Before the age of twenty he had formally dedicated himself to God; and at the close of his university course he became a minister of the French Protestant Church. The great work of his

life, however, did not commence until, in 1767, he was appointed to the curacy of Waldbach in the valley of Ban de la Roche in Alsace. He then found himself among a few ignorant and half-savage parishioners, who were shut up from the civilized world within the cold bosom of their native mountains, were scattered over a stony uncultivated valley, lived upon wild apples and pears, and shivered in filthy cabins of turf. His first act was an attempt to induce the natives to open up their country by making regular highways. But he soon found that all his ardent expositions of the advantages of trade could not excite their sluggish desires. He therefore seized a mattock, and began to make a road with his own hands. This action struck the peasants like an electric shock. They could not stand idly by while their delicately-nurtured pastor was sweating in their behalf: young and old came flocking to give their assistance; highways began to traverse the valley; a bridge was thrown over a turbulent stream that interrupted all intercourse with Strasburg; and in a short time commerce was beginning to circulate through the country. The same mode of teaching by example was used to introduce agriculture. The pastor brought a patch of ground that was by the wayside under cultivation; the fine crop, as it grew ripe, excited the envy of all that passed by; they came in crowds to learn the secret of his agriculture; he gave them both instruction and assistance; and the result was that the desert of Waldbach soon began to "blossom as the rose." To improve the domestic economy of his parishioners was the next endeavour of Oberlin; and he did it like one who, after the example of the Divine Master, deems it a sacred task to relieve even the meanest want of humanity. He assisted the men in building comfortable cottages; despatched the idle boys to the neighbouring districts to learn farming or the mechanical trades; set the unemployed girls to knitting, straw-plaiting, and cotton-spinning; and instructed the housewives in using certain common plants for food and medicine. The love and gratitude which the natives felt for all these benefits, opened their hearts to receive the higher lessons of their pastor. His homely sermons on Sabbath, his prayer-meetings during the week, his habit of blending religion with all the duties of common life, and his humble and active piety—all contributed to soften down their rough and stubborn dispositions. He induced them to start an itinerant library, to establish the first specimens of infant schools that had ever existed, and to build an ordinary school at each of the five villages in the parish. It was not even thought impertinent when he kept a register of their moral characters, and inquired into the most paltry of their family affairs. In fact, he had now come to be considered the father of his flock; and no circumstance in his large household was thought too trifling to demand his loving attention. The latter half of Oberlin's life was spent in superintending the social organization which he had established in his parish, in entertaining the many pious individuals who came from different parts of Europe to visit him, in circulating copies of the Bible throughout France, and in advancing the cause of missions in heathen countries. He died on the 1st June 1826, and was interred with great honour, and in the presence of a great concourse of people, at the village of Foudai. The name of Oberlin was associated for some time afterwards with the active piety of Louisa Schepler, a humble woman, who had lived in his house for fifty years in the capacity of servant and housekeeper. This simple-hearted peasant continued till her death in 1837 to teach in the schools of the valley, to consecrate all her little earnings to Christian charity, and to wait without remuneration on the children of her beloved master. (*Brief Memorials of Oberlin*, by the Rev. Thomas Sims, M.A., London, 1830; and *Memoirs of Oberlin, with a Short Notice of Louisa Schepler*, London, 1838 and 1852.)

Object.

OBERLIN, *Jeremie Jacques*, a learned antiquary and philologist, the elder brother of the preceding, was born at Strasburg in 1735, and entered the university of his native place. His career was distinguished from the very first by an unwearied devotion to antiquarian research. At the end of his philosophical course, he produced a thesis, entitled *De Veterum Ritu Condiendi Mortuos*. Then, commencing a theological curriculum, he turned his attention exclusively to the archæology of the sacred writings. Nor were his favourite studies discontinued when he was appointed assistant and successor to his father in the laborious duties of an elementary teacher in the gymnasium. He requested and obtained permission from the university of Strasburg to deliver a course of lectures on the Latin tongue; he prelected and published manuals on archæology and ancient geography; and he made frequent excursions into various provinces of France to investigate the antiquarian remains and the provincial dialects of the country. At length, in 1782, his appointment to the chair of logic and metaphysics at Strasburg brought his philosophical activity into full play. He published *Dissertations sur les Minnesingers* in 1782-89; an edition of Horace in 1788; and *Observations concernant le Patois et les Mœurs des Gens de la Campagne* in 1791. The troubles of the French revolution interrupted his studies; and in 1793 he was imprisoned for some time at Metz; but on the restoration of tranquillity he returned with fresh zest to his books. His edition of Tacitus appeared in 1801; and his edition of Cæsar in 1805. He was engaged in editing Justin, when he was cut off by a stroke of apoplexy in 1806.

OBERNAI, or **OBEREHNHEIM**, a town of France, in the department of Lower Rhine, 14 miles N. of Schelestadt. It is ill built; and has a large town-hall, college, and hospital; while in the vicinity are the ruins of a palace and a convent. Calico, leather, hats, soap, bricks, earthenware, nails, &c., are made here. The town was once fortified; and has sustained several sieges. Pop. 5356.

OBIDOS, a fortified town of Portugal, province of Estremadura, stands on the Arnoia, where it enters the lagoon of Obidos, 47 miles N. by W. of Lisbon. It has some ancient remains; and is remarkable for a victory gained here by the British under Wellington over the French, 15th August 1808. Pop. 3000.

OBJECT AND OBJECTIVE, **SUBJECT AND SUBJECTIVE**, are two pairs of correlative terms, much used in philosophical speculation, and not always free from ambiguity. The foundation of this capital distinction in philosophical terminology is to be found in the ultimate analysis of knowledge itself, of which philosophy lays claim to be the science. For if knowledge is the result of a relation between that which knows (the subject) and that which is known (the object), it follows that the terms Subject and Subjective, Object and Objective, stand forth as opposing contraries, to mark off compendiously the grand, the fundamental distinction which lies at the root of all knowledge. The general discrimination indicated by those terms is at once articulate and precise; but in their special application they are liable to ambiguity and equivocation. The Subject, as now commonly employed by philosophers, denotes that which knows; and is limited exclusively to the Ego, or conscious mind, called by the Germans *Das Ich*, and by the French *Le Moi*. Subjective, is employed in like manner to express what pertains to the mind, the Ego or thinking principle. The terms Object and Objective, again, are employed generally in contrast and correlation to these, to denote that which is known, the Non-ego, with its modes and properties, called by the Germans *Das Nicht-Ich*, and by the French *Le Non-Moi*. But it is obvious that the terms Subjective and Objective, while generally distinguishing what belongs to mind from what belongs to

Oblate
||
Obojan.

matter, are not quite thorough and unambiguous in their discrimination. For the object known is not of necessity a mode of what is called matter, or of the Non-ego. If I am conscious of joy or sorrow, for example, or call before my imagination the representation of a distant object, it is obvious that what the mind contemplates is, in this case, wholly in and of itself—is as emphatically a mode of the Ego as extension is of the Non-ego. But if the phenomena of the thinking subject can thus become objectified, so to speak, and converted into the object known, there at once emerges a palpable equivocation in the use of the terms Object and Subject. This ambiguity may be effectually avoided, however, by coupling with those terms a qualifying attribute when it is necessary to do so. While, therefore, Subject and Subjective should be employed in their simplicity to denote what belongs to, or is dependent on, the knowing mind, whether of man in general or of some man in particular; and Object and Objective to express what does not so belong or depend; some nomenclature is requisite to mark off precisely an object of knowledge as a mode of mind on the one hand, or as something different from mind on the other. "Without, therefore," says Sir William Hamilton, "disturbing the preceding nomenclature, which is not only ratified but convenient, I would propose that, when we wish to be precise, or when any ambiguity is to be dreaded, we should employ, on the one hand, either the terms *subject-object*, or *subjective object* (and this we could again distinguish as absolute or as relative); on the other, either *object-object* or *objective object*." With respect to the alternative indicated above parenthetically of the absolute or relative element in subjective objects, he remarks in another place, "But the *subject-object* may be either a mode of mind of which we are conscious as absolute, and for itself alone,—as, for example, a pain or pleasure; or a mode of mind of which we are conscious as relative to, and representative of, something else,—as, for instance, the imagination of something past or present. Of these we might distinguish, when necessary, the one as the *absolute* or the *real subject-object*; the other as the *relative* or the *ideal*, or the *representative subject-object*. Finally, it may be required to mark whether the *object-object* and the *subject-object* be immediately known as present, or only as represented. In this case we must resort, on the former alternative to the epithet *presentative* or *intuitive*; on the latter to those of *represented*, *mediate*, *remote*, *primary*, *principal*," &c. See Hamilton's edition of Reid, note B; in which there will be found a historical and critical exposition of the use of these terms in the Greek and scholastic philosophy. (See also *Dictionnaire des Sciences Philosophiques*.)

It may not be improper to observe, that the words Subject and Object, besides possessing the technical signification just described, are also used in a popular sense entirely different. Thus, in the expression "subject of discourse," the word "subject" is employed for the *materia circa quam*, where object would be exclusively applied in philosophy. *Object* is also vulgarly used, both in France and England, for *end*, *motive*, *final cause*, &c.

OBLATE, flattened or shortened, as an oblate spheroid, having its axis shorter than its middle diameter, and being formed by the rotation of an ellipse about its shorter axis. The earth, the polar diameter of which is shorter than the equatorial, is an oblate spheroid.

OBLIQUE signifies generally something aslant, or deviating from the perpendicular. Thus an oblique angle is either acute or obtuse; that is, any angle except a right one.

OBLONG, in general, denotes a figure the length of which exceeds the breadth; as, for example, a parallelogram.

O BOLUS, an ancient Greek coin. (See **NUMISMATICS**.)

OBOJAN, a town of Russia, in the government of

Observa-
tories
||
Occam.

Kursk, stands at the confluence of the Obojanka and Psiol, 36 miles S. of Kursk, and about 370 W.S.W. of Moscow. It is well built; has several churches, schools, and hospitals; and drives a flourishing trade in cattle, wax, &c. Pop. (1849) 4968.

OBSERVATORIES. (See *ASTRONOMY, Supplement* to part i.)

OBY, a small island in the Malay Archipelago, S. of Gilolo; S. Lat. 1. 30., E. Long. 127. 50. It is about 50 miles in length, and varies from 10 to 20 in breadth. It has lofty mountains and dense woods, and yields spices and sago. The Dutch have a settlement at the west end; and near this is another island called Little Oby.

OCANA, a town of Spain, in the province of Toledo, 35 miles S. of Madrid, and 26 E. of Toledo. It is an ancient town, built on the sides and top of a hill, and is surrounded by ruinous walls. The streets are narrow and ill built, but there are several handsome squares, churches, convents, schools, an hospital, and a prison. The town is supplied with water by a stone aqueduct of nineteen arches, supposed to have been built by the Romans. Manufactures of soap, bricks, earthenware, cloth, &c., are carried on. In the neighbourhood the Spaniards sustained in 1809 a signal defeat from the French. Pop. 4789.

OCANA, a town of New Granada, capital of a province of the same name in the department of Guanenta, on the Oro, 60 miles N.W. of Pamplona. It stands among the Andes; and there are copper mines in the vicinity. Some trade is carried on by the River Oro and the Canaverales, into which it falls. Pop. of town, 5500; of province, 23,450.

OCCAM, or **OCKHAM**, **WILLIAM OF**, an English scholastic philosopher, and the great champion of Nominalism in the fourteenth century, was born at Ockham in Surrey in the latter half of the thirteenth century. He repaired to Paris at an early age, having been expelled from Oxford for exciting tumults among the students. On reaching that city he joined the ranks of the Franciscans, and sat at the feet of their great chief, Duns Scotus, "the most subtle Doctor." Nothing is known respecting Occam until he appeared as a public teacher in Paris. In this capacity he produced an extraordinary sensation. By the boldness of his speculations and the vehemence of his dialectics, mere tradition, no matter how venerable, whether political, religious, or philosophical, found no quarter with William of Occam. "The invincible Doctor," as he soon proved himself, threw the weight of his influence, as the advocate of Nominalism and free opinion, and the sworn foe of Realism and intellectual submission, on the side of Philip the Fair of France in his contest with Pope Boniface VIII. William published a celebrated manifesto in favour of the cause, entitled *Disputatio super potestate ecclesiastica praelatis atque principibus terrarum commissa*, which the successor of St Peter did not at all relish. The author and his followers were branded as innovators in the church as well as in the schools; and Nominalism became with the ecclesiastical party another name for heresy. On the death of Boniface, Pope John XXII. summoned Occam and his disciples before him at Avignon, and the "invincible Doctor" only escaped the vengeance of his Holiness by a precipitate flight to Bavaria, on the 26th of May 1328. Here he gained the protection of Louis, and remained till his death, which took place at Munich some twenty years afterwards. (For the doctrines of Occam, see **NOMINALISM** and **REALISM**.)

The following writings compose Occam's philosophical works:—*Super libros Sententiarum subtilissimas questiones*, fol., Lyon, 1495, in which will be found the substance of the author's metaphysical doctrines; *Quodlibeta septem*, fol., Paris, 1487, and Strasburg, 1491; *Summa logices*, 4to, Venezia, 1591, and frequently reprinted; *Major summa logices*, 4to, Venezia, 1522; *Questiones in libros Physicorum*, fol., Strasburg, 1491, 1506; *Expositio aurea super totam artem veterem, videlicet in Porphyrii prædicabilia et Aristotelis prædicamenta*, fol., Bologna, 1496.

OCCULTATION is that phenomenon in which a star or planet becomes concealed from our view by the intervention of the moon. (See *ASTRONOMY*.)

Oculation
||
Ochino.

OCCUPANCY, in *Law*, is the taking possession of that which before belonged to no one in particular. This, according to Blackstone (*Commentaries*, b. ii., c. 16), is the true ground and foundation of all property, or of holding those things in severalty which by the law of nature, unqualified by that of society, were common to all mankind.

OCEAN. See *PHYSICAL GEOGRAPHY*.

OCEANIA. See *AUSTRALASIA*.

OCEANUS, an ancient Greek god, was the son of Uranus and Gæa, and the eldest of the Titans. Homer and Hesiod represent him as a divinity of might and importance, and they each mention several elements in his greatness. He was the father, by Tethys, of the rivers, and of the 3000 Oceanides, the goddesses of the rivers; he dwelt in a palace in the far west; and "the ocean stream" over which he ruled encircled the whole earth, and touched the vault of heaven on every side.

OCELLUS LUCANUS, a Pythagorean philosopher, born in Lucania in Italy, as his name implies, and supposed to have flourished during the fifth century B.C. He is said to have been a contemporary as well as a disciple of Pythagoras. The only definite information we possess respecting Ocellus—and even that is not of the most authentic character—is to be found in two letters cited by Diogenes Laërtius (lib. viii., c. 80, 81), in which Archytas sends Plato a reading of four works of the Lucanian philosopher. Plato, in acknowledging the receipt of the precious MSS., expresses his admiration of their contents. These books contained treatises on Law, on Kingly Rule, on Piety, and on the Nature of the Universe. Of these writings, the only one which has come down to us is the last, entitled *Περὶ τῆς τοῦ παντὸς φύσεως*; written originally in Doric Greek; but the authorship of it is by no means clear. The best editions are those of Rudolphi, Leipsic, 8vo, 1801; and of Mullach, Berlin, 1846. The Marquis D'Argens published an 8vo edition at Berlin, 1762, with a French translation and a commentary. There is a good edition by Batteux, 3 vols. 12mo, Paris, 1768; and an English version of Ocellus was published in 8vo, 1831, by Thos. Taylor.

OCHINO, or **OCHINUS**, **BERNARDINO**, a famous Italian ecclesiastic, was born at Sienna in 1487, and assumed the monkish garb at an early age. After living for some time among the Franciscans, he passed over to the Capuchins, and was elevated in 1537 to the rank of general of that order. From that time Ochino was distinguished for his bold and earnest self-devotion to whatever he considered his duty. His simple and touching eloquence was zealously exerted in behalf of the church and his own order; none of the favours which admiring princes attempted to heap upon him could excite his cupidity; and he was content to be known throughout Italy as an itinerant preacher and a squalid, emaciated ascetic. In 1541, when the truth of the Protestant doctrines dawned upon him, he did not hesitate to cast away the great popularity he had gained in the Church of Rome, and to become a fugitive and a wanderer for the sake of his honest conviction. After taking refuge in Geneva and Augsburg, he found an asylum in England, in 1547. The accession of Mary in 1553 drove him back to the Continent; and not until 1555 did he obtain a permanent footing as minister of an Italian church at Zurich. Before eight years had passed, his fearless avowal of his opinions brought him once more into trouble. Happening, in a volume of dialogues which he published, to maintain that polygamy was lawful under certain circumstances, he was driven forth from Switzerland in mid-winter to find another home. He retreated into Poland; but no heretics could remain there. Worn out with age and travel, he

Ochil Hills turned to go into Moravia: the plague overtook him at Slawkow, and he died in 1564.

O'Connell, Daniel. Ochino was the author of a collection of sermons, which was published in Italian, at Basle, in 5 vols. 8vo, 1562. Several of them have been translated at different times into English. He also wrote commentaries on the epistles to the Romans and Galatians, and some pamphlets against Popery.

OCHIL HILLS, a mountain range of Scotland, in the county of Perth, about 24 miles in length, and having an average breadth of 12 miles. They extend from within 2 miles of the Forth, near Stirling, in a N.E. direction, to the Firth of Tay. The highest point is Bencleugh, at the S.W. extremity, 2300 feet above the level of the sea. The geological formation is basalt and greenstone, probably covering Silurian formations; and iron and copper ores have been found. The greater part of the hills afford good pasturage for sheep.

OCKLEY, SIMON, an eminent orientalist, and professor of Arabic in Cambridge, was born at Exeter in 1678. He was educated at Cambridge, and distinguished himself by uncommon skill in the oriental languages. Having taken a degree in divinity, he was, in 1705, presented by Jesus College with the vicarage of Swavesey, and in 1711 he was chosen Arabic professor of the university. He had a large family, and his latter days were rendered unhappy by pecuniary embarrassments. He died in the year 1720. The principal works of Ockley are, *Introductio ad Linguas Orientales*, 1706; *The History of the Jews throughout the World*, from the Italian of Leo of Modena, 1707; *The Improvement of Human Reason*, from the Arabic, 1708; *The History of the Saracens*, in 2 vols. 8vo, 1708-18. This last work was compiled from Arabic manuscripts in the Bodleian Library at Oxford, and is justly valued for its accuracy and erudition.

OCLISEER, a town of British India, in the district of Broach, presidency of Bombay, 35 miles N. of Surat, and 50 miles S. of Baroda, on the route between these two towns. Pop. 7000.

O'CONNELL, DANIEL, a celebrated political agitator, was born at Carhen, in the neighbourhood of Cahirciveen, in the county of Kerry, on the 6th of August 1775. He was descended from an old Roman Catholic family in his native county, who could boast more of the antiquity of their descent than of the affluence of their circumstances. His father, Morgan O'Connell, if not a rich man, possessed at least a tolerable competence, the fruits of his own industry and prudence; and enjoyed the advantage, during those stirring times, of comparative seclusion amid the romantic wilds of Kerry. Daniel received his first lesson from a poor old hedge-schoolmaster, who being engaged on a begging expedition, took a fancy for the child, and is said to have taught him his alphabet at a single sitting. At the age of thirteen O'Connell was sent to a school at Redington, Long Island, near Cove, conducted by a Catholic priest named Harrington. After spending a year at this institution without, according to Fagan, giving much indication of superior talent, young O'Connell and his brother were removed by their uncle Maurice, who had adopted the lads, with the design of being sent to some suitable place of learning on the Continent. They accordingly entered the Jesuit's college of St Omer's in France in 1791, and after remaining a year there, they removed to the English college of Douai. At the former institution Daniel seems to have carried all before him, and the principal, Dr Stapylton, wrote of him when leaving, "I never was so much mistaken in my life as I shall be, unless he be destined to make a remarkable figure in society." The outbreak of the French revolution brought their studies to a close, and the two young Irishmen turned their faces towards England the same day the unfortunate Louis lost his head at Paris. The atrocities of the Reign of Terror

produced a strong impression on the mind of O'Connell; and he had no sooner got on board the English packet-boat at Calais than he plucked the tricolor cockade from his cap, trampled it under his feet, and flung it into the sea. He returned to Ireland, he said, almost a "Tory at heart." During his absence the rigour of the penal laws against Roman Catholics had become somewhat relaxed; and the profession of law was now thrown open to the Catholic as well as the Protestant. O'Connell resolved to prepare himself for the Irish bar, and became a student at one of the Inns of Court in London in 1794. He was called to the bar in 1798, and commenced a most brilliant career as a legal pleader. Politics do not seem to have occupied much of his public attention at this period, and he even held aloof from the wild and unscrupulous revolutionists of his time. The policy which subsequently guided his public life had already taken hold of his mind. "He would accept of no social amelioration at the cost of a single drop of blood."

O'Connell made his first public appearance at a political meeting held by the Catholics of Dublin in the Royal Exchange Hall, on the 13th of January 1800, to petition against the proposed union of the English and Irish legislatures. In this short speech are to be found in germ the fundamental ideas of his public life. There is a certain stiffness and formality about it, doubtless incidental to youth and inexperience; but it is pervaded by a sturdy energy and clear-headed determination which gives solidity to his patriotic indignation, and commands instant respect. From this period O'Connell gradually assumes a leading place among the political agitators of the day. In 1802 he was privately married to his cousin Mary, daughter of Dr O'Connell of Tralee. The disastrous insurrection of 1803, known as "Emmett's rebellion," found O'Connell enrolled among the "lawyer's infantry" in the general arming which then took place. The calamitous results of that unhappy movement, and the temporary cruelties which it entailed, served more and more to inflame the passions of the disaffected, and gave an increasing prominence to the "Catholic question." The "Catholic Board," having incurred the displeasure of the government, was dissolved by proclamation in 1804; but the zeal and activity of its adherents succeeded in reviving it soon after under the title of the "Catholic Committee." Regular reports of the debates of this body are to be found in the Dublin newspapers from 1808. O'Connell, who was now in good practice, and who seems to have been regarded as the most promising barrister of the day, directed his surprising energies more systematically and continuously to the cause of the Roman Catholics; and became the acknowledged leader of political reform in Ireland. It is to this period of his life that O'Connell alludes in his pamphlet written in reply to the attack of Lord Shrewsbury in 1842, when he rebuts the taunt of receiving "the rent," as it was called, in the following words:—"For more than twenty years before emancipation, the burden of the cause was thrown upon me. I had to arrange the meetings, to prepare the resolutions, to furnish replies to the correspondence, to examine the case of each person complaining of practical grievances, to rouse the torpid, to animate the lukewarm, to control the violent and the inflammatory, to avoid the shoals and breakers of the law, to guard against multiplied treachery, and at all times to oppose, at every peril, the powerful and multitudinous enemies of the cause. . . . At that period, and for more than twenty years, there was no day that I did not devote from one to two hours, often much more, to the working out of the Catholic cause, and that without receiving or allowing the offer of any remuneration, even for the personal expenditure incurred in the agitation of the cause itself." The most painful occurrence, of a personal kind, of O'Connell's entire career took place

O'Connell,
Daniel.

O'Connell,
Daniel.

in 1815. Having applied the term "beggary" in one of his speeches to the Dublin corporation, one of the members of that body, Mr D'Esterre, came forth in defence of its injured dignity, and demanded satisfaction from the agitator. A duel followed, which ultimately proved fatal to D'Esterre. O'Connell never ceased to express the most painful regret at the issue of this melancholy affair. Beyond the general indication just given of the services rendered by him to the cherished cause, nothing of very special importance in O'Connell's career demands attention until the summer of 1828, when the decisive struggle for Roman Catholic emancipation had reached its crisis. A vacancy having occurred in the representation of the county of Clare in the month of June of that year, O'Connell was proposed as a candidate, despite his adherence to the Roman Catholic faith, and was returned to Parliament by a great majority. On reaching Westminster, he refused to take the oaths, which had been framed with the express design of excluding Roman Catholics. The attitude which he assumed had the effect of bringing the civil disabilities of his party prominently before the nation. A year passed away full of keen and noisy debate, both in and out of Parliament, without any decisive result; yet the influence of intelligent public opinion, even among Protestants, was waxing so strong in favour of Catholic emancipation, that the following year witnessed the repeal of the last of those civil disabilities to which Roman Catholics had been so long and so unjustly subjected. O'Connell took his seat as a member of Parliament in May 1829. Here he seems to have been both feared and disliked, and was received by the House with the most icy coldness. The day came, however, when his matchless oratorical powers were recognised, and he ultimately became perhaps the most attractive debater in the House of Commons. (See an excellent sketch of the public speakers of that period in the *New Monthly Magazine* for 1832.) The career of O'Connell is of necessity so much interwoven with the public history of the time, from his entry upon his parliamentary duties, that the reader will find his subsequent history placed in the most intelligible light by referring to the articles BRITAIN, and IRELAND. At the general election in 1830 he was returned for his native Kerry. He represented Dublin from 1832 to 1835, when he was unseated. The following year he sat for Kilkenny; in 1837 he was once more returned for the capital; and in 1841 he was chosen representative of the county of Cork. The Conservatives came into power in 1841, and the great Irish agitation in behalf of the repeal of the Union began to assume a formidable character. "Monster meetings" were held all over the country. The "rent," or annual subscription for the support of the "Liberator" and the cause of repeal, poured in in the most cheering manner; and O'Connell strove to unite all Irishmen in the struggle. He announced in the Repeal Association—"1843 is, and shall be, the great repeal year." Spots rendered sacred by tradition and song were chosen as rallying-points for the indignant display of popular independence; and the royal hill of Tara, the curragh of Kildare, and the rath of Mullaghmast, shook with the noisy patriotism of thousands upon thousands of wild ignorant Irishmen. The chief laid aside for a time the dignified eloquence of the senator, and adopted a style better adapted to captivate the hearts of his admiring fellow-countrymen. Like Nestor of old in the camp of the Greeks, "the words distilled from his lips like honey;" but it is to be feared there was more "blarney" than wisdom in them. No man knew better than O'Connell what to say, and when to say it; and if he treated the House of Commons to splendid displays of fiery logic, impassioned invective, and brilliant retort, he knew well where a slight touch of swagger gave a man a kingly air, where a rare joke went farther than a good argument,

where big words passed for wisdom, and loud ones for courage. "The great Irish people" who believed in repeal were down on their knees before the "Liberator:" his heart was cheered within him; and out of the abundance of his generosity he made the most liberal promises. "I hope," he said, "to be able to give you, as a New Year's gift, a Parliament in College Green." Other cheer awaited that festive season, however. Another "monster meeting" was projected at Clontarf, three miles from Dublin, at which the choice of those swaggering patriots were to appear on horseback, and parade before the idle and applauding multitude as the glorious "Repeal Cavalry." But the Irish government failed to sympathize with this grand conception; and the iron hand of power was lifted menacingly in the face of repeal. The prohibitory proclamation of government was followed up by a peaceful recommendation from the "Liberator," who always strove to steer clear of a physical collision. This proclamation was issued on the 7th of October 1843, and ere seven days had passed, the Chief and a number of the leading repealers were arrested on a charge of conspiracy and sedition. O'Connell had, throughout his entire career as a political agitator, manifested the most consummate skill and self-command in constantly treading on the very verge of constitutionalism, and yet always keeping within the bounds of strict legal activity. Attempts had previously been made to convict him of sedition, but to no purpose. But the flush of success of "the great repeal year" apparently threw him off his guard, and the "Liberator" was now within the clutches of the law. After a trial of twenty-four days, the Irish judges sentenced O'Connell to imprisonment for twelve months, with a fine of £2,000, and bound him over to keep the peace for seven years. The judgment was carried before the House of Lords, and the decision of the Irish judges was reversed. This trial had the effect of dissolving the charm exercised by the "Liberator" in Ireland: it well nigh beggared the Repeal Association, and indeed gave the death-blow to the entire movement. O'Connell's doctrine of the absolute renunciation of physical force in seeking political amelioration met with no favour at the hands of the "Young Ireland" party; and in 1846 they seceded from a leader who had been the champion of the cause for forty years. The Irish famine was only needed to break the spirit of the indomitable O'Connell. With failing health and a heavy heart, he set out on a devotional pilgrimage to Rome in 1847, but he had only reached Genoa, when he was suddenly called to lay down his load on the 15th of May of the same year. At his own request, his heart was embalmed and borne to Rome, and his body was carried back to the land which he had loved so well. He left three daughters and four sons to lament his loss. His eldest son Maurice, for many years the representative of Tralee, died in 1853. The *Memoir on Ireland* written by O'Connell never got beyond the first volume.

(See the *Life and Speeches of Daniel O'Connell, M.P.*, by his son, John O'Connell, M.P., 2 vols., 1846; *The Life and Times of Daniel O'Connell*, by William Fagan, M.P., 2 vols., 1847; *Personal Recollections of Daniel O'Connell*, by Daunt, 2 vols., 1848; *Last Days of Daniel O'Connell*, by Maccabe, 1847.) (J. D.—S.)

OCTAGON, an eight-sided polygon. (See GEOMETRY.)

OCTAHEDRON, one of the five regular solids contained by eight equal and equilateral triangles. (See GEOMETRY, part ii.)

OCTAVIA, the youngest daughter of Caius Octavius, and the sister of Augustus. She was the widow of Caius Marcellus in 40 B.C., when her brother and Mark Antony concluded their recent variances by a formal treaty of agreement. Her marriage with the latter was then proposed as a means of still further strengthening the union between the two triumvirs. To save her country from

Octagon
||
Octavia.

Octavia
||
Ode.

civil broils, and to please her brother, the noble-minded matron sacrificed herself, and wedded the notorious libertine. It soon appeared that along with her hand she had given her life's devotion. As long as Antony remained at home, her wisdom, her virtues, and the charms of her mature beauty, were zealously employed to keep him on good terms with Octavianus. When he deserted her in 36 B.C., for the syren charms of Cleopatra, her conjugal fidelity remained unabated. In the following year she set out for Egypt to endeavour to regain his vagrant affections; on receiving at Athens an order from him to return home, she immediately obeyed; and it was not until, in 32 B.C., he sent her a bill of divorce, that she could be prevailed upon to leave his house in Rome. Even after his death in 30 B.C., she did not think that her obligations to serve him were at an end. She continued to bring up his younger son by his first wife Fulvia; and when his children by Cleopatra were brought to Rome to grace the triumph of Octavianus, she adopted them into her own family. Octavia had now for several years been constantly attended by misfortune; but the great and the closing sorrow of her life was yet to come. In 23 B.C. Marcellus, her son by her first husband, the idol of the Roman people, and the heir-presumptive to the empire, died at the age of twenty. She fell into a state of melancholy, which continued till her death in 11 B.C.

The great worth of Octavia was celebrated by a public interment, and by a funeral oration delivered by her imperial brother. Her memory was preserved by a magnificent edifice built by Augustus, and called "Porticus Octaviæ."

OCTAVIA, the grand-daughter of the preceding, was the daughter of the Emperor Claudius and Messalina, and was born about 42 A.D. Her short life was a series of the most cruel wrongs. At the age of six she was betrothed to Lucius Silanus, a young man of noble birth. About her eleventh year this betrothal had been nullified by the designs of her step-mother, the infamous Agrippina; and she was married to Nero, the son of the latter, and the heir to the empire. Nine years afterwards Nero, by that time emperor, divorced her on the charge of sterility, in order to make room for Poppæa. The innocent young princess next became the victim of the systematic vengeance of her triumphant rival. An attempt was first made to force her servants to accuse her of incontinency; but not even the torture could wring from them a word against the reputation of their mistress. She was then exiled into Campania; but the people soon brought her back to Rome in triumph. At length the slave Anicetus was hired to procure her condemnation, by swearing that he had been her paramour. The helpless girl, in her twentieth year, was immediately taken away to the island of Pandataria to be put to death. Her veins were opened by the soldiers; extreme fear, however, prevented the blood from flowing; and it was found necessary to stifle her in the steam of a hot bath. The woes of Octavia form the subject of a tragedy found among the works of Seneca, and they have also been dramatized by Alfieri.

OCTOBER, in chronology, the eighth month, as the name implies, of the old Roman year; but the tenth in the calendar of Numa, Julius Cæsar, &c. The senate gave this month the name of *Faustinus*, in compliment to Faustina, the wife of the Emperor Antoninus; Commodus wished it to be called *Invictus*; and Domitian named it *Domitianus*; but in spite of all these attempts it still retains its original name. This month was sacred to Mars; and a horse, called the *October Equus*, was annually sacrificed to that deity. A race was run with chariots previously to the sacrifices, when the fleetest horse was made the victim.

ODE, a short lyrical poem containing a vivid expression of the feelings of the poet in moments of high excitement. Among the Greeks and Romans the ode (*ὕμνη, a song*) was intended to be sung, and was usually accompanied by some

musical instrument, especially the lyre. Hence the expression "lyric poetry," of which the earliest forms seem to have been the ode. The most celebrated classical odes are those of Pindar, Anacreon, and Horace, which are still recognised by the moderns as models in that species of poetical composition. In the modern use of the word, however, the ode differs, on the one hand, from the song, by greater length and variety, and by not being necessarily adapted to music; and, on the other, from the ballad, by generally excluding narrative, and limiting its range exclusively to the expression of feeling or passion on a given subject. In English literature the odes of Dryden, Gray, and Collins are much esteemed. (See POETRY.)

ODEIPORE, a raj of British India, under the jurisdiction of the political agent for the S.W. frontier of Bengal; N. Lat. (of centre) 22. 40., E. Long. 83. 23.; area 2306 square miles. This territory was forfeited to the British government on account of the systematic crimes of the rajah, and the want of direct heirs. The annual revenue is estimated at L.1500. Pop. 133,000. The chief town is Odeipore, 183 miles S. of Benares, and 320 W. of Calcutta.

ODENATHUS, a famous prince of Palmyra, and husband of the celebrated Zenobia. (See PALMYRA.)

ODENSE, a seaport-town of Denmark, capital of the island of Funen, on the N. bank of the Odense-Aue, a small stream flowing into the fiord of the same name, 88 miles W. by S. of Copenhagen. It is one of the oldest places in Denmark, and is said to have been founded by Odin, whose grave is shown about a quarter of a mile to the N. of the town. The cathedral, in the Gothic style, founded by Canute IV. in 1080, and completed in 1301, is one of the finest ecclesiastical buildings in Denmark, and contains the tombs of several Danish kings. There are here also an old episcopal palace, a royal palace, a town-hall, several schools, a theatre, two public libraries, an hospital, &c. The manufactories of the place consist of breweries, distilleries, iron-foundries, and woollen mills; and some trade is carried on, which is facilitated by several harbours near the town. Pop. (1851) 11,122.

ODENSWALD, a range of mountains of Western Germany, in Hesse-Darmstadt, stretching northwards from Heidelberg to Darmstadt. Its length is about 45 miles; and the highest point is the Katzenbuckel, 2300 feet above the sea. The western slopes consist of granite and gneiss, and the eastern of sandstone. The higher elevations are well wooded, and the lower regions cultivated. Several remains of Roman forts exist here.

ODER, a river of Europe, rises in Moravia, about 15 miles E. of Olmütz, flows N.E. to the confines of Prussia, then turns to the N.W., and flows generally in that direction as far as Oderberg in Brandenburg, where it turns to the N.E., and discharges its waters through the Grosse Haff into the Baltic. Its whole length is 550 miles; and it is navigable for vessels of 50 tons as far as Breslau, and for small boats up to Ratibor in Prussian Silesia. It receives from the right the Malapane, Bartsch, and Wartha; and from the left the Oppa, Silesian and Bohemian Neisse, Katzbach, and Bober. The principal towns on its banks are Breslau, Glogau, Frankfort, Custrin, and Stettin. This river is connected by canals with the Elbe, the Spree, and the Vistula.

ODESSA, a town of European Russia, in the government of Kherson, stands on the north-western shore of the Black Sea, 90 miles W.S.W. of Kherson, and 390 N. of Constantinople; N. Lat. 46. 28., E. Long. 30. 43. Placed between the mouths of the Dniester and Bug, and not far from that of the Dnieper, the site is very favourable for commerce.

From the reign of Peter the Great, Russia had been steadily looking forward to a maritime preponderance, both

||
Odessa.

Odessa.

military and commercial, in the Black Sea; and soon after the peace of Jassy, by which the province of Kherson was ceded to Catharine, that princess selected as the place for a commercial emporium a village called Kodschabeg, then inhabited only by a few fishermen. The town was founded in 1794; and the first settlers were a number of Greek families, who were induced to remove thither from other portions of the country which had been recently given up by the Turks. When the Emperor Alexander I. ascended the throne, he entered with zeal into the project which Catharine had formed. The French emigrant Duke of Richelieu, who had entered the Russian service, was appointed governor, and displayed great zeal and judgment. Under his administration Odessa rapidly rose in prosperity; so that by the year 1804 the inhabitants had increased to the number of 15,000. A fortress, a lighthouse, and a lazaretto, were constructed, as well as a mole to secure 300 sail of vessels from the S.W. winds, which sometimes blow with prodigious force. In 1817 the inhabitants were exempted from taxes for thirty years; and the port was declared to be an open one. All goods of every kind could now be imported without duty for the consumption of the city, or for re-exportation, but were chargeable with duty on passing into the surrounding country. This gave a great impetus to its advancement, which still operates. During the late Russian war the batteries of Odessa fired upon the *Furious*, a British steam-frigate under a flag of truce, on the 14th of April 1854; and as no reparation was made for this breach of the laws of war, a squadron of the allied fleet bombarded the place on the 22d of April, and greatly injured the fort, the batteries on the moles, and the vessels in the harbour. On the 12th of May the steam-frigate *Tiger*, which ran aground in a fog, was fired at by the artillery of Odessa. The vessel was destroyed, the captain mortally wounded, and the crew captured.

The prosperity of Odessa has risen in a great measure from its maritime accessibility. It has a spacious bay, which, though open to the easterly winds, is tolerably secure; it is very extensive, and the anchorage ground is good. There is a kind of harbour formed by two moles, about two-thirds of a mile in length, and a handsome quay capable of accommodating 300 vessels. The town is regularly built; the streets are wide and straight; and the houses are for the most part built of stone, and two stories in height. The streets are, however, but partially paved. Odessa is defended by a strong citadel on the N.E., which has a double ditch and also several outworks; and there are also batteries on the moles and on the shore between them. Among the public edifices, the most conspicuous is the cathedral, a large and elegant pile. There are a number of other churches for the Greek worship; and the Jews, Roman Catholics, and German Lutherans have their respective places of worship. A college has been established, with a museum and botanic garden. The admiralty, hospital, exchange, and theatre (where plays, in the Russian and Greek languages, and Italian operas, are performed), are fine buildings. The town has several schools, a lazaretto, barracks, and the governor's house, containing the public offices. Along the quay runs a boulevard, lined with handsome houses, and adorned with a statue of Richelieu. Most of the water is brackish; and to provide that necessary element in purity, an aqueduct has been constructed at great expense, which conveys it from a distance of nearly 20 miles. The climate is healthy, though the summer is intensely hot. Winter is short, but severe, the sea being more or less frozen for about two months.

The rapid growth of Odessa depends wholly upon its commerce, the sources of which are to be found in the fertility of its surrounding soil and that of the more distant districts, to which there is easy access. The steppes, which

form a semicircle around Odessa, extend to nearly 100 miles from the city. This district is destitute of trees and of running water, but the soil is said to be favourable to the growth of corn, especially of wheat. There are many gardens and vineyards in the vicinity of Odessa; and the melons raised here form a favourite article of food.

The soil of the districts bordering upon the northern side of the steppes, even with the negligent husbandry it receives, is most abundantly productive of wheat. Indeed, there is no part of the world known in which, in propitious seasons, the increase of grain is so great. It is, however, liable to great variations in its growth, and sometimes years occur when the increase is very insignificant. The quantities of wheat exported from Odessa in each year from 1847 to 1852 may be seen from the following table:—

Years.	Qrs.	Years.	Qrs.
1847	2,016,692	1850	980,377
1848	1,409,963	1851	718,325
1849	1,127,000	1852	1,362,251

The quantity of Indian corn exported in 1852 was 225,635 qrs.; of rye, 216,229 qrs.; of barley, 35,102 qrs.; of oats, 6918 qrs.; and of pulse, 4291 qrs. The corn of Odessa is for the most part conveyed to the coasts and islands of the Mediterranean, and also in large quantities to Britain, to which there were exported from this place in 1852, 570,237 qrs. of wheat, 222,276 of Indian corn, 3644 of rye, 23,875 of barley, 1296 of oats, and 404 of peas. Of linseed there were exported in 1852, 135,880 qrs.; of tallow, 38,575 cwt.; of candles, 5688 cwt.; of wool of various sorts, 74,864 cwt.; of hides, raw and dressed, 1877 cwt.; of copper, 8133 cwt.; and of cables and cordage, 13,227 cwt. To the United Kingdom were exported, in 1852, 83,050 qrs. of linseed, and 16,450 cwt. of wool, besides smaller quantities of other articles. The total value of the exports from Odessa was estimated in 1852 at L.3,976,754. The imports consist chiefly of wine, porter, rum, sugar, tobacco, fruits, lead, tin, zinc, coals, hardware, machinery, and linen, woollen, silk, and cotton goods. The total value of the articles imported in 1852 was estimated at L.1,637,895. The number of vessels that entered the port in 1851 was 698, and the tonnage 196,218, including 126 British vessels, with a tonnage of 37,531. The number that cleared was 729; tonnage, 203,842; and among these, 130 British, tonnage, 38,830.

The inhabitants are of very mixed races, but consist chiefly of Russians, Greeks, and Jews. German handicraftsmen are also to be found amongst them in considerable numbers; whilst the more extensive mercantile houses are composed of Italians, English, French, or Armenians. In no spot perhaps in Europe are there so great a number of languages spoken as on the exchange of Odessa. The admixture of oriental dresses, manners, and languages presents a very novel and lively picture; and the bazaars contain all the productions of the East, from Persian shawls down to rose-pastilles. Pop. (1850) 71,392.

ODIHAM, a market-town of Hampshire, England, 37 miles N.E. of Southampton. It stands on the N. side of a chalk down, and consists of a well-built main street and two others of smaller size. The parish church is an old brick edifice, with a square tower. There are remains of an ancient palace, and a ruined castle in which David I. of Scotland was imprisoned for eleven years. Lily the grammarian was born at Odiham in 1468. Pop. (1851) of the parish 2811.

ODIN, the supreme divinity of the ancient Scandinavians. (See MYTHOLOGY.)

ODOACER, the first barbarian king of Italy, was the son of Edecon, the minister of Attila. In 476 he wrested the sceptre from the hands of Romulus Augustulus, the last Roman emperor of the West; and in 493 he was deposed and assassinated by Theodric the Ostrogoth. (See ITALY.)

ODONTOLOGY.

INTRODUCTION.

Introduction.

Definition.

ODONTOLOGY¹ is that branch of anatomical science which treats of the teeth. The term "tooth" has been applied in Zoology and Zootomy to various organs and parts; usually to such as are so solid, so shaped, and so situated in animal bodies, as to serve for seizing and operating on the food; but it has been also applied to parts, such as the prominences on the hinge of bivalve shells, which have no relation to the digestive function. The silicious spines of infusory animalcules, the calcareous jaws of sea-urchins, the chitinous hooks and hooklets of sea-worms, and many corresponding parts of invertebrate animals, are described as "teeth;" but the present essay exclusively relates to those bodies, hardened chiefly by the phosphate of lime, which are attached to parts of the mouth or beginning of the alimentary canal, and which are peculiar to the vertebrate classes of animals.

The term "tooth" is immediately derived from the Teutonic word *tunth*, which we may trace through the old English or Anglo-Saxon *tain*, the Danish *tand*, the German *zahn*, the Latin *dens*, the French *dent*, the Italian *dente*, the Greek *odous*, *odontes*, the Welsh *dant*, the Erse *dend*, and the Lithuanic *dantis*, to the Sanscrit mother-root *dantas*; these synonymes being strikingly illustrative of the coincidence, in one of the primary words, of a natural class of languages which prevails from Central Asia, westward, over Europe, and of the unity of stock of the great Indo-European family of mankind.

True calcified teeth are primarily, if not permanently, distinct parts from the bony skeleton, and are exposed, save where their development is prematurely arrested, as, *e.g.*, in the rudimental tusk of the narwhal. The exceptions to their calcified condition in the Vertebrata are very few; such, *e.g.*, as the horny teeth in the Myxinoid fishes and the Monotremes. But true calcified teeth vary in their tissue and composition, and still more in regard to number, size, form, structure, position, and mode of attachment in different animals. They are principally adapted for seizing, tearing, dividing, pounding, or grinding the food: in some they are modified, to serve as weapons of offence and defence; in others as aids to locomotion, means of anchorage, instruments for uprooting or cutting down trees, or for transport and working of building materials. They are characteristic of age and sex; and, in man, they have secondary relations subservient to beauty and to speech.

Teeth are always most intimately related to the food and habits of the animal, and are therefore highly interesting to the physiologist. They form, for the same reason, most important guides to the naturalist in the classification of animals; and their value as zoological characters is enhanced by the facility with which, from their position, they can be examined in living or recent animals; whilst the durability of their tissues renders them not less available to the palæontologist in the determination of the nature and affinities of extinct species, of whose organization they are often the sole remains discoverable in the deposits of former periods of the earth's history.

Teeth are composed of a cellular and tubular basis of

animal matter containing earthy particles, a fluid, and a vascular pulp. In general, the earth is present in such quantity as to render the tooth harder than bone, in which case the animal basis is gelatinous, as in other hard parts where a great proportion of earth is combined with animal matter. In the very few instances among the vertebrate animals above cited, where the hardening material exists in a much smaller proportion, the animal basis is albuminous; the teeth here agree, in both chemical and physical qualities, with horn.

Teeth rarely consist, like bones, of a uniform or nearly uniform substance, but are composed to two or more tissues, characterized by the proportions of their earthy and animal constituents, and by the size, form, and direction of the cavities in the animal basis which contain the earth, the fluid, or the vascular pulp. The tissue which forms the body of the tooth is called "dentine" (Lat. *dentinum*; Germ. *zahnbein*, *zahnsubstanz*; Fr. *l'ivoire*); (fig. 1, *d*). The tissue which forms the outer crust of the tooth is called "cement" (Lat. *cementum*, *crusta petrosa*); (figs. 1 and 5, *c*). The third tissue, when present, is situated between the dentine and cement, and is called "enamel" (Lat. *encaustum*, *adamas*); (figs. 1 and 5, *e*).

Dentine consists of an organized animal basis, and of earthy particles: the basis is disposed in the form of compartments (fig. 3, *a*), of minute tubes (fig. 3, *d*), and cells (fig. 3, *g*); the particles have a twofold arrangement, being either blended with the animal matter of the interspaces (*c*) and parietes (*d*) of the tubes and cells, or being contained in a minutely granular state in their cavities. The density of the dentine arises principally from the proportion of earth in the former of these states of combination. The tubes and cells contain, besides the granular earth, a colourless fluid, probably "plasma," or "liquor sanguinis," in a delicate cellular tissue, and thus relate not only to the mechanical conditions of the tooth, but to the vitality and nutrition of the dentine.

Approximative steps to the recognition of the true nature of teeth were made by Purkinjé² and Retzius;³ but the first definite and unequivocal announcement of the observed organic connection between the vascular and vital soft parts of the frame and the hard substance of a tooth, was communicated to the Institute of France in 1839.⁴ "If the

Introduction.

Nature of tooth.

pulp of a growing tooth be submitted to microscopical examination, and compared with a pulp before it has begun to be calcified, it will be seen to be not covered by any outer membrane, like the so-called 'membrana propria,' or the smooth dense covering of the uncalcified pulp; but the surface of the pulp, from which the calcified sheath has been removed, will appear cottony and villous: in proportion as the tooth is more advanced in its formation, it becomes more difficult to separate the calcified from the non-calcified part of the pulp, and at the same time more easy to discover the continuation of the prolongations of the pulp in the interior of the numerous medullary canals which constitute so many distinct centres of radiation for the plexiform dentinal tubes." This discovery of the organic connection between the pulp and the canals of the dentine, made by observation of the development of the teeth of the shark, was affirmed to be applicable to the teeth of Mammalia: it was only the excessive smallness of the dentinal tubes in the latter which rendered invisible to the naked eye the irregularity of the uncalcified surface of the pulp, when the calcified part was detached in a growing tooth. The apparent smoothness of such exposed surface was illusory.

Dr Schwann, in his important essay on the correspondence in structure and development between animals and plants,¹ spoke of the "presumed" transition of the cells of the pulp into the dentinal tubes, which he calls "fibres," but leaves that capital fact as one still of uncertainty, and questionable. The author of the present article published the full evidence of his original propositions, above cited, in his work entitled *Odontography*, 4to, 1840-1845, and was able to give more direct testimony of the continuation of filamentary processes of the pulp into the minute tubes of hard dentine, on the occasion of anatomizing a full-grown male elephant in 1850. "I had the tusk and pulp of the great elephant at the Zoological Gardens longitudinally divided, soon after the death of that animal in the summer of 1847. Although the pulp could be easily detached from the inner surface of the pulp-cavity, it was not without a certain resistance, and when the edges of the co-adapted pulp and tooth were examined by a strong lens, the filamentary processes from the outer surface of the pulp could be seen stretching, as they were withdrawn from the dentinal tubes, before they broke. They are so minute that, to the naked eye, the detached surface of the pulp seems to be entire, and Cuvier was thus deceived in concluding that there was no organic connection between the pulp and the ivory."²

Confirmatory evidence of the continuation of filamentary processes of the pulp into the dentinal tubuli in the human teeth, has recently been communicated to the Royal Society of London by Mr Tomes.³ It has appeared to the present writer that the filamentary processes of the pulp

become resolved, at or near the first bifurcation of the tubuli, into mere delicate membranous linings of the dentinal tubes, which are chiefly occupied by the plasma contained in these continuations of the pulp, with occasional detached calcareous particles.

Until a comparatively recent period, the analogy of dentine to bone was supposed to be confined to their chemical constitution, and the nature of the hardening material; while the arrangement, as well as the mode of deposition of the tooth-tissue, were considered to be wholly different from that of bone; and the dentine to agree, in its general nature and mode of growth, with hair and other extravascular horny parts, with which most teeth closely correspond in their vital properties.⁴

The structure of a tooth, in fact, was regarded as simply laminated, and the ivory was described as being formed layer within layer, deposited by, and moulded upon, the formative superficies of the vascular pulp. The illustrations and supposed proof of this structure and mode of growth were derived from the apparently detached condition of the newly-formed particles of dentine on the pulp's surface, when exposed by the removal of the calcified part of the tooth; from the appearance observed in the teeth of animals fed alternately with madder and ordinary food, which undoubtedly illustrate the true progress of dental development; from the illusory traces of laminated structure observed in vertical sections of teeth when viewed with the naked eye, or with a low magnifying power; and lastly, and chiefly, from the successive hollow cones into which a large tooth, such as the elephant's tusk, is commonly resolved in the process of decomposition.

With regard, however, to the appearances presented by the teeth of animals under the influence of madder, and the separation of the dentine into superimposed lamellæ during decomposition, the same conclusions, as to intimate structure and mode of development, might be drawn respecting true bone, which also commonly resolves itself into the concentric lamellæ during decomposition, and presents the same appearance of alternate white and red layers in animals fed alternately with madder and ordinary food during the progress of its growth. The lines running parallel to each other, and to the contour of the crown, presented by the cut surfaces of vertical sections of teeth, especially of the elephant's tusk, or of the tooth of the cachalot, are due to a totally different structure from that to which they are ascribed. The lamellated arrangement, thus seemingly demonstrated, is, moreover, far from being a constant appearance; on the contrary, the superficies of vertically cut or fractured surfaces of the human and most other teeth offer a very different character, and one which has led to many approximations and allusions to the true structure of dentine, in the works of anatomists who have recorded their own original observations.

longements du bulbe dans l'intérieur de ces nombreux canaux médullaires qui constituent tant de centres de radiation distincte pour les tubes calcigères plexiformes. Le principe du développement dentaire s'effectuant par dépôt dans la substance et non par exsudation en dehors de la substance d'un bulbe pré-existant, tel qu'il ressort de la dentition des squales, est d'une application sans effort, naturelle et manifeste à la formation des dents des mammifères. Dans l'ivoire d'une dent simple de mammifère, il existe un canal médullaire unique, appelé cavité du bulbe, et un système unique de tubes rayonnés calcigères; mais le plan et la mode de formation sont les mêmes que dans les squales." "Les tubes calcigères d'une dent de mammifère ont des parois distinctes tant dans les portions calcifiées que dans les portions non calcifiées du bulbe. Ces parois sont rendues fragiles par le dépôt qui s'y fait de particules terreuses dans la portion calcifiée du bulbe, et alors se séparent facilement de leur portion non calcifiée, laquelle se continue dans le reste du bulbe, et c'est l'excessive petitesse des tubes rompus qui rend invisible à l'œil nu l'irrégularité de la surface du bulbe: mais cette apparence d'une surface naturelle libre, exsudante, n'est qu'une illusion." (*Recherches sur la structure et la formation des dents des Squaloïdes, et application des faits observés à une nouvelle théorie du développement des dents*, par M. R. Owen; *Comptes Rendus des Séances de l'Académie des Sciences*, No. 25, 16 Décembre 1839, p. 786.

Introduc-
tion.
Structure.

Whoever attentively observes a polished section or a fractured surface of a human tooth, may learn, even with the naked eye, that the silky and iridescent lustre reflected from it in certain directions is due to the presence of a fine fibrous structure.

Malpighi, in whose works may be detected the germs of many important anatomical truths that have subsequently been matured and established, says, that the teeth consists of two parts, of which the internal bony layers (dentine) seem to be composed of fibrous, and, as it were, tendinous capillaments reticularly interwoven.¹ Retzius cites many recent authors—e.g., Sæmmering, Schreger,² and Weber³—who mention the silky, glistening lustre of the dentine; and Frederick Cuvier, in the preliminary discourse of his admirable work, the *Dents des Mammifères*, observes, “Les dents de l’homme, de singes, de carnassiers, ont un ivoire d’apparence soyeuse, qui semble formé de fibres” (p. 27). These intelligible hints of the true structure of the dentine, which the foregoing observers received from a superficial but unprejudiced inspection, failed, however, to incite them to a closer interrogation of nature in regard to the dental tissues. One of her most persevering investigators had, nevertheless, long before obtained a true and definite answer to his more direct inquiries. Leeuwenhoek having applied his microscopical observations to the structure of the teeth, discovered that the apparent fibres were really tubes, and he communicated a brief but succinct account of his discovery to the Royal Society of London, which was published, together with a figure of the tube, in the 140th number of their *Transactions*. This figure of the dentinal tubes, with additional observations, again appears in the Latin edition of Leeuwenhoek’s Works, published at Leyden in 1730. The dental substance (dentine) of the human teeth, and of those taken from young hogs, is described as “being formed of tubuli spreading from the cavity in the centre to the circumference.”⁴ Fig. 2 is accurately copied from Leeuwenhoek’s original figure, intended to represent the general arrangement of these tubuli in the human molar tooth. The Dutch microscopist computed that he saw 120 of the tubuli within the forty-fifth part of an inch.⁵ Leeuwenhoek also shows that he was aware of the peculiar substance, distinct from the ivory and enamel, and now termed the cement, or *crusta petrosa*, which enters into the composition of the teeth of the horse and ox;⁶ a component part of the tooth which Hunter speaks of as a second kind of bone, and which was first accurately and specifically described by Tenon⁷ and Blake.⁸

Fig. 2.
Section of Human Molar Tooth; after Leeuwenhoek.

The discovery of Leeuwenhoek that the dentine was made up of very minute tubes, which proceeded from the inner to the outer surface of the tooth, was confirmed by Purkinjé⁹ so far as regarded their existence; but Purkinjé added an exact and particular account of the direction of these tubes in the human dentine, and showed that, in addition to them, the dentine contained an intermediate or intertubular tissue. This he describes as homogeneous and

without structure, and as entering into the composition of the dentine in a greater proportion than the tubes themselves. The more extensive, varied, and minute observations of Professor Retzius¹⁰ led to the discovery of the cells of the intertubular tissue of the ramuli (fig. 3, f), sent

off from the main dentinal tubes (fig. 3, d), into that tissue, and of the anastomoses of the ramuli with each other (fig. 3, b), with the intertubular cells, and with the cells at the periphery of the dentine (fig. 3, g). According to the researches of Dr Schwann,¹¹ the animal basis of the intertubular tissues possesses a fibrous structure. Besides the primary and secondary branches of the dentinal tubes, Retzius first clearly described their curvatures and undulations, which may be defined as follows:—As a general rule, the dentinal tubes are directed, as affirmed by Leeuwenhoek and Purkinjé, from the inner to the outer surface of the tooth, and vertically to those surfaces, as shown in the section of the human incisive tooth (fig. 4), and of the molar tooth (fig. 1, at d, d). But in their course the tubes describe two, three, or more curvatures, appreciable by a low magnifying power. These are termed the “primary curvatures.”¹² With a higher power, the tubes are seen to be bent throughout the whole of their flexuous course into minute and oblique undulations or gyrations (fig. 3, d), 200 of which were counted by Retzius in one-tenth part of an inch length of a human dentinal tube; these are termed the “secondary curvatures” or gyrations.¹³ Both the primary and secondary curvatures of one dentinal tube are usually parallel with those of the contiguous tubes; and from the radiated course of these tubes, they occasion the appearance of lines running parallel with the ex-

sues.

ternal contour of the tooth; for, when the surface of a longitudinal section of a tooth is viewed with the naked eye, the light is differently reflected from the different parts of the oblique secondary curves of the tube on which it falls; but the curves being parallel to each other, and to the superficial contour of the section, they appear like the cut edges of a series of parallel and superimposed lamellæ. In many teeth, moreover, and especially in the tusks of the elephant, the secondary branches of the dentinal tubes dilate into intertubular cells; along lines which, in like manner, are parallel to the coronal contour of the tooth: hence another cause of the appearance of concentric lamellæ, and of the actual decomposition of such teeth into superimposed lamelliform cones. Such appearances and modes of decomposition are peculiar to the dense or unvascular dentine, but are by no means common to that modification of the tissue. Varieties of form, such as the occasional aneurismal-like dilatations of the dentinal tubuli, as shown at *e* (fig. 3), have been figured by that accurate and minute investigator of the pathology of the human teeth, Mr S. J. A. Salter, in the *Transactions of the Pathological Society of London* for 1855, pl. i., fig. 3. In fig. 3 the delicate filamentary prolongations of the pulp are represented at *d, d*; the dentinal compartments, or indications of the original cells of the dentinal pulp are shown at *a, a*; and the modified peripheral layer of the dentine at *g*, to the superior sensibility of which M. Duval first called attention, distinguishing it by the name of "dictyodonte."¹

Such is the typical structure of dentine, which structure relates, in regard to the curvilinear compartments, *a, a* (fig. 3), to the steps in its formation; and in regard to its tubular columns, to the strength of the tooth and its vitality; the latter important property depending on the percolation of the plasma through the delicate cellular structure of the filamentary prolongations of the pulp, so far as they may extend along the tubuli. The sensibility of the dentine is due to concomitant productions of neurine; but the distinct tubules are not large enough to admit capillary vessels with red particles of blood, and the tissue above described has consequently been sometimes termed "unvascular dentine."

The simplest modification of dentine is that in which capillary tracts of the primitive vascular pulp remain uncalcified, and permanently carry red blood into the substance of the tooth. These so-called medullary canals (more properly "vascular canals"), present various dispositions in the dentine, which they modify, and which modification is called "vasodentine."² It is often combined with true dentine in the same tooth; *e.g.*, in the scalpriform incisors of certain rodents,³ the tusks of the elephant,⁴ the molars of the extinct *Iguanodon*.⁵ A third modification of the fundamental tissue of the tooth is where the cellular basis of the dentine is arranged in concentric layers around the vascular canals, and contains radiated cells like those of osseous tissues; it is called "osteodentine."

The tissue called "cement" closely corresponds with osteodentine and with the osseous tissue of the skeleton of the same animal in which it is found; and wherever it occurs of sufficient thickness, as upon the teeth of the horse (fig. 5, *c*), sloth (fig. 9, *c*), or ruminant, it is also traversed, like bone, by vascular canals. In reptiles and mammals, in which the animal basis of the bones of the

skeleton is excavated by minute radiated cells, forming with their contents the "corpuscles of Purkinjé," these are likewise present, of similar size and form, in the "cement;" and are its chief characteristic as a constituent of the tooth. The hardening material of the cement is partly segregated and combined with the parietes of the radiated cells and canals; and is partly contained in disgregated granules in the cells, which are thus rendered white and opaque viewed by reflected light.

The relative density of the dentine and cement varies according to the proportion of the earthy matter, and chiefly of that part which is combined with the animal matter in the walls of the cavities, as compared with the size and number of the cavities themselves. In the complex grinders of the elephant (fig. 140), the wart-hog (fig. 121), the voles (fig. 88), and the capybara, the cement *c*, which forms nearly half the mass of the tooth, wears down sooner than the dentine.

The "enamel" is the hardest constituent of a tooth, and consequently the hardest of animal tissues; but it consists, like the other dental substances, of earthy matter arranged by organic forces in an animal matrix. Here, however, the earth is mainly contained in the canals of the animal membrane; and, in mammals and reptiles, completely fills those canals which are comparatively wide, whilst their parietes are of extreme tenuity. The hardening salts of the enamel are not only present in far greater proportion than in the other dental tissues; but in some animals are peculiarly distinguished by the presence of a small proportion of fluoate of lime.

The examples are extremely few, and confined to cold-blooded animals, of calcified teeth which consist of a single tissue; and this is always a modification of dentine. The maxillary denticles of the parrot-fish (*Scarus*), and the large pharyngeal teeth of the wrasse (*Labrus*), consist of a very hard kind of unvascular dentine. Fig. 6 shows a vertical section of one of the latter teeth, supported upon the vascular osseous tissue of the pharyngeal bone; *p* is the pulp cavity.

The next stage of complexity is where a portion of the dentine is modified by vascular canals. Teeth thus composed of dentine and vaso-dentine are very common in fishes. The hard dentine is always external, and holds the place, and performs the office, of enamel in the teeth of

¹ *Observations Anatomiques sur l'Ivoire*, 8vo, Paris, 1838, p. 14. "Souvent les molaires sont tellement usées que, au lieu d'être tuberculeuse, leur face triturante est lisse par l'effet de la dévotion. On y distingue parfaitement, comme après la coupe transversale d'une dent, les aspects sous lesquels se présentent ses substances dures; l'un appartient à l'émail qui est très-blanc; le second à la substance osseuse, que je désigne sous le nom d'*osteodonte*; et le troisième à cette partie qui, sous forme de zone circulaire et de couleur de corne, se trouve entre ce dernier et l'émail, et que j'appelle *dictyodonte*. Si avec la pointe d'un cure-dent d'acier, ou d'une sonde, on touche une de ces parties, l'émail ne donne aucun signe de sensibilité, l'*osteodonte* quelquefois un peu, mais le *dictyodonte* beaucoup et plus souvent. (Duval, *Observations Pratiques sur la Sensibilité des Dents*, 8vo, 1833, p. 7.)

² This substance was first characterized as a component of tooth distinct from ivory, enamel, cement, and true bone, and as easily recognizable, in a paper by the author, communicated to the British Association in 1838, *loc. cit.* p. 137.

constituent so predominates that it takes a polish like enamel,

for which it has commonly been mistaken in the teeth of fishes; it is called "vitrodentine."

The molars of the dugong are examples of teeth composed of dentine and cement; the latter tissue forming a thick external layer. Fig. 8 shows a transverse section of

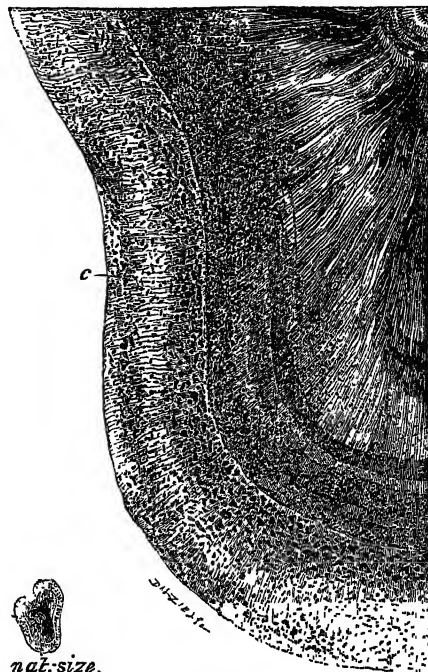

Fig. 8.

the crown of the second molar, natural size, and above it a magnified view of a portion of the section; in which *d* is the dentine, remarkable for the number of minute calciferous cells at its periphery, and *c* is the cement. A small portion of osteodentine usually occupies the centre of the crown at *o*. In the large teeth of the lower jaw of the cachalot (*Physeter*) the pulp-cavity of the growing tooth becomes filled up by osteodentine, the result of a modified calcification of the dentinal pulp; and the full-grown tooth presents three tissues, as shown in fig. 62, in which *c* is the thick external cement, *d* the hard dentine, and *o* the osteodentine: the latter is sometimes developed into stalactitic-shaped nodules, loose in the pulp-cavity.

In the teeth of the sloth, and of its great extinct congener the megatherium, the hard dentine is reduced to a thin layer, and the chief bulk of the tooth is made up of a central body of vasodentine, and a thick external crust of cement. Fig. 9 represents a longitudinal section of a lower molar of the three-toed sloth (*Bradypus tridactylus*) magnified; *v* is the vasodentine, *d* is the hard dentine, and *c* is the cement; *p* is the apex of the wide persistent pulp-cavity. In the megatherium the hard dentine, which is the firmest tissue, forms the transverse ridge of the grinding surface (fig. 54, *d*), like the enamel-plates in the elephant's grinder: it has consequently been described to be enamel,² but its relation to that tissue is only one of analogy or function.

The human teeth, and those of the carnivorous mammals, appear at first sight to be composed of dentine and enamel only, as they were described to be by the Cuviers,³ who called them therefore "simple teeth;" but their crowns are originally, and their fangs are always, covered by a thin coat of cement. There is also commonly a small central tract

views are given of longitudinal sections of a human incisor and molar tooth, in which *d* is the dentine, *e* the enamel, and *c* the cement.

The teeth called by Cuvier "compound" or "complex" in Mammalia, differ, as regards their composition, from the preceding only by the different proportion and disposition of the constituent tissues. Fig. 10 is a longitudinal section of the incisor of a horse; *d* is the dentine, *e* is the enamel, and *c* the cement; *c'* is the layer of cement reflected into the deep central depression of the crown, usually occupied by a coloured mass of tartar and particles of food, forming the "mark" of the horse-dealer. The characteristic structure of the three tissues—*d* dentine, *e* enamel, *c* cement—is shown in the magnified part of the section in fig. 5.

A very complex tooth may be formed out of two tissues by the way in which they are interblended as the result of an original complex disposition of the constituents of the dental matrix. The teeth of certain fishes, and of a singular extinct family of gigantic sauroid Batrachians, called "Labyrinthodonts,"¹ exhibit, as the name implies, a remarkable instance of this kind of complexity. Fig. 11 is a view of a canine tooth of the *Labyrinthodon salamandroides*, of the natural size; and fig. 12 is a slightly magnified view of a transverse section across the part of the crown marked *a*. At first view the tooth appears to be of the simple conical kind, with the exterior surface merely striated longitudinally, but every such streak

Horse.

is a fissure into which the very thin external layer of cement is reflected into the body of the tooth, where it follows the sinous wavings of the lobes of dentine which diverge from the central pulp-cavity *pp*. The inflected fold of cement *c* runs straight for about half a line, and then becomes wavy, the waves rapidly increasing in breadth as they recede from the periphery of the tooth: the first two, three, or four undulations are simple; then their contour itself becomes broken by smaller or secondary waves; these become stronger as the fold approaches the centre of the tooth, when it increases in thickness, and finally terminates by a slight dilatation or loop close to the pulp-cavity, from which the free margin of the inflected fold of cement is separated by an extremely thin layer of dentine. The number of the inflected converging folds of dentine is about fifty at the middle of the crown of the tooth figured, but is greater at the base. All the inflected folds of cement at the base of the tooth have the same complicated disposition with increased extent; but as they approach their termination towards the upper part of the tooth, they gradually diminish in breadth, and consequently penetrate to a

dually diminish in breadth, and consequently penetrate to a

¹ Proceedings of the Geological Society, January 20, 1841, p. 257.

Introduction. less distance into the substance of the tooth. Hence, in such a section as is delineated, it will be observed that some of the convoluted folds, as those marked *c*, extend to near the centre of the tooth; others, as those marked *c'*, reach only about half way to the centre; and those folds, *c''*, which, to use a geological expression, are "cropping out," penetrate to a very short distance into the dentine, and resemble in their extent and simplicity the converging folds of cement in the pulp of the tooth of the *Ichthyosaurus*. The disposition of the dentine is still more complicated than that of the cement. It consists of a slender central conical column, excavated by a conical pulp-cavity for a certain distance from the base of the tooth; and that column sends radiating outwards from the circumference a series of vertical plates, which divide into two once or twice before they terminate at the periphery of the tooth. Each of these diverging and dichotomizing plates gives off throughout its course smaller processes, which stand at right angles, or nearly so, to the main plate; they are generally opposite, but sometimes alternate; many of the secondary plates or processes which are given off near the centre of the tooth also divide into two before they terminate, and their contour is seen in the transverse section to partake of all the undulations of the folds of cement which invest and divide the dentinal plates and processes from each other. The dental pulp-cavity is reduced to a mere line about the upper third of the tooth, but throughout its whole extent fissures radiate from it corresponding in number with the radiating plates of dentine. Each fissure is continued along the middle of each bifurcation and process to within a short distance of the line of cement. The pulp-fissure commonly dilates into a canal at the origin of the lateral processes of the radiating plates, before it divides to accompany and penetrate those processes. The main fissures or radiations of the pulp-cavity extend to within a line or half a line of the periphery of the tooth, and suddenly dilate at their terminations into spaces, which in transverse section are subcircular, oval, or pyriform (*p*); the branches of the radiating lines, which are continued into the lateral secondary plates or processes of the dentinal lamellæ, likewise dilate into similar and generally smaller spaces. All these spaces or canals in the living tooth, must have been occupied by corresponding processes of the vascular pulp; they constitute so many centres of radiation of the fine calciferous tubes, which, with their uniting clear substance, constitute the dentine.¹

An analogous complexity is produced by numerous fissures radiating from a central mass of vasodentine, which more or less fills up the pulp-cavity of the seemingly simple conical teeth of the extinct family of fishes called "Dendrodonts," characterizing the Old Red Sandstone, or Devonian system.

Fig. 13 is one of these fossil teeth of the natural size—*a*, a transverse section; and fig. 14 a reduced view of a portion of the same section enlarged twenty diameters. Thus magnified, a central pulp-cavity of relatively small size, and of an irregular lobulated form, is discerned, a portion of which is shown at *p*; this is immediately surrounded by transverse sections of large cylindrical vascular or pulp canals of different sizes; and beyond these there are smaller and

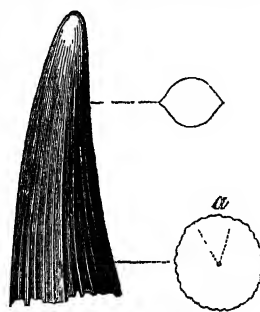

Fig. 13.
Tooth of *Dendrodus biporcatus*
(nat. size).

more numerous medullary canals, which are processes of the central pulp-cavity. In the transverse section these processes are seen to be connected together by a net-work of smaller vascular canals belonging to a coarse osseous

Dental tissues.

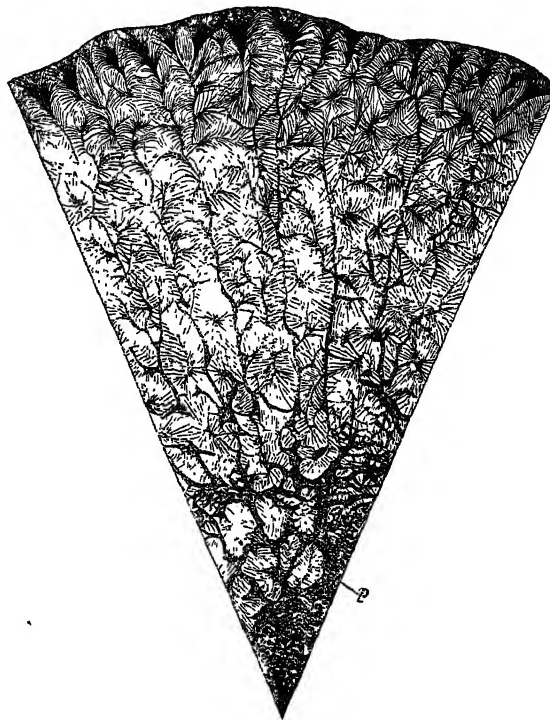

Fig. 14.

Magn. section of part of *Dendrodus biporcatus*.

texture, into which the pulp has been converted, and this structure occupies the middle half of the section. All the vascular canals were filled up by the opaque matrix. From the circumference of the central net-work straight pulp-fissures radiate at pretty regular intervals to the periphery of the tooth; most of these fissures divide once, rarely twice, in their course,—the division taking place sometimes at their origin, in others at different distances from their terminations,—and the branches diverge slightly as they proceed. Each of the above pulp-canals or fissures is continued from a short process of the central structure, which is connected by a concave line with the adjoining process, so that the whole periphery of the transverse section of the central coarse reticulo-vascular body of the tooth presents a crenate outline. From each ray and its primary dichotomous divisions short branches are sent off at brief intervals, generally at right angles with the trunk, or slightly inclined towards the periphery of the tooth. These subdivide into a few short ramifications like the branches of a shrub, and terminate in irregular and somewhat angular dilations simulating leaves, but which resolve themselves into radiating fasciculi of minute dentinal tubes. There are from fifteen to twenty-five or thirty-six of these short and small lateral branches on each side of the medullary rays.

A third kind of complication is produced by an aggregation of many simple teeth into a single mass.

The examples of these truly compound teeth² are most common in this class of fishes, but the illustration here selected is from the mammalian class. Each tooth of the Cape ant-eater (*Orycteropus*, fig. 15) presents a simple form; is deeply set in the jaws, but without dividing into

Introduction.

Dental tissues.

fangs; its broad and flat base is porous, like the section of a common cane. The canals to which these pores lead contain processes of a vascular pulp, and are the centres of radiation of as many independent series of dentinal tubules. Each tooth, in fact, consists of a congeries of long and slender prismatic denticles of dentine, which are cemented together by their ossified capsules, the columnar denticles slightly decreasing in diameter, and occasionally bifurcating as they approach the grinding surface of the tooth. A figure of a longitudinal section of the molar teeth is given in pl. 76, fig. 10, of the author's *Odontography*. Fig. 15 gives a magnified view of a portion of the transverse section of the fourth molar, showing *c* the cement, *d* the dentine, and *p* the pulp-cavity of the denticles.

The pectinated incisors of the flying lemur of the Indian Islands (*Galeopithecus*, fig. 86) are examples of teeth the crowns of which are composed of denticles consisting of hard dentine, with a covering of true enamel. The layer of cement over this is too thin to show its characteristic structure, and does not fill up the intervals of the denticles, which stand out as free processes from the base of the crown. Tubular prolongations of the pulp-cavity are continued up the centre of each denticle. The originally detached summits of the crown of the human incisor are homologous with these columnar processes or denticles of the incisor of the *Galeopithecus*. In the compound molars of the great African wart-hog (*Phacochoerus*), the columnar denticles are in three rows, and their interspaces are filled up by cement; each denticle consists of a slender column of hard dentine inclosed in a thick sheet of enamel, the whole being bound together by the cement; and the denticles, as in the *Galeopithecus*, blend together into a common base in the fully-developed tooth. A figure is given of the grinding surface of the third true molar of the *Phacochoerus Pallasii* in fig. 121.

In the elephant the denticles of the compound molars are in the form of plates, vertical to the grinding surface, and transverse to the long diameter of the tooth (figs. 140, 141). When the tooth is bisected vertically and lengthwise, the three substances—*d* dentine, *e* enamel, and *c* cement—are seen interblended.

A still more complex grinding apparatus is found in certain fishes. The lower pharyngeal bone of the parrot-fish (*Scarus*), for example, supports a dental plate with a triturating surface, like that of the compound molars of the *Phacochoerus*; the interlocked upper pharyngeals (fig. 35) support dental masses with a grinding surface, more like that of the compound molars of the elephant. When a vertical and longitudinal section is made of one of these upper pharyngeal compound teeth, each denticle is seen to be composed of a body of very hard and unvascular dentine, with a thick sheath of enamel, the denticles being united together by the cement, and supported and further united together, and to the pharyngeal bone, by a basal mass of vascular osteodentine. When worn down by the trituration of hard corals to this basis,

four alternating kinds of dental tissue, of varying degrees of density, and of corresponding variations of level, are exposed in this fish.¹

Such are some of the prominent features of a field of observation which comparative anatomy opens to our view, —such the varied nature, and such the gradation of complexity of the dental tissues, which, up to December 1839, continued, notwithstanding successive approximations to the truth, to be described in systematic works as a "*Phaneros*, or a dead part or product exhaled from the surface of a formative bulb."²

In the development of a tooth, a matrix or formative organ, corresponding in complexity with the kind of tooth to be formed, is first developed. It consists either of a soft vascular papilla,—a free conical process,—as in certain fishes (fig. 24, *c*), which mold of the future simple tooth is called its "pulp," or the "dentinal pulp;" or it consists of the "pulp" inclosed in a "capsule;" or of a pulp with such a modification of a peripheral part, situated between the pulp proper and the capsule, as to merit a distinct definition as an "enamel organ." The first and most constant of these parts is termed the "dentinal pulp" (fig. 16, *p*); the second is the capsule, or "cemental pulp" (fig. 16, *c*); the third is the "enamel pulp" (fig. 16, *e*).

The linear cavity in the gums of the embryo, in which the pulps of the first series of teeth are formed, is termed the "primary dental groove;" where the first are succeeded by a second set of teeth, the pulps of these teeth are developed in a distinct recess, called the "secondary dental groove."

In man a certain proportion only of the teeth developed in the primary groove are displaced by teeth developed in a secondary groove; and the twenty teeth, so displaced, are called "milk-teeth," or deciduous teeth. The teeth of the molar series developed in the secondary groove are called "premolars," or bicuspid. The true molars are a continuation of the primary series, and are only "permanent," inasmuch as those of the secondary series are not co-extensive with them in number and position in the jaws. The differentiation of teeth, according to place and order of development, is illustrated (fig. 17) in the lower jaw of a young

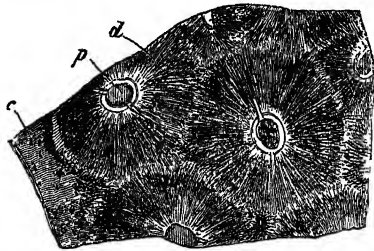

Fig. 15.
Magn. section of a part of the Compound Tooth of the *Orycteropus*.

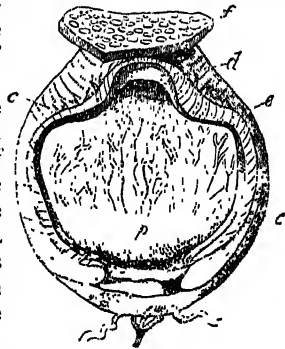

Fig. 16.
Matrix of a Human Tooth (magn.)

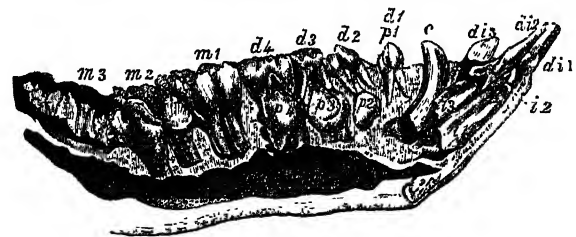

Fig. 17.
Section of Lower Jaw of a young Hog, showing the Teeth in course of formation. The teeth of the grinding series marked *d* 1 to *d* 4, *m* 1 to *m* 3, are successively developed from before backwards in the primary groove; the teeth marked *p* 2 to *p* 4 are developed in the secondary groove, as are also the successors of the canines and incisors. Both grooves

fonds, que dans quelque sens qu'on coupe la dent, on coupe plusieurs fois chacune des substances qui la composent; telles sont les dents molaires de l'éléphant." The teeth of the 'Labyrinthodonts' would come under this definition more truly than those of the elephant, although they differ from them in having no enamel; for a molar of an elephant might be bisected vertically and transversely without cutting the tissues across more than once.

¹ Numerous other modifications of dental structure will be found described and figured in the author's *Odontography*, 4to, 1840-45.

² De Blainville, *Ontogénie*, passim.

Introduction.

are converted into a closed chamber, and then subdivided into as many "formative cavities" as teeth, in the progress of dental development. The proper tissue of the dentinal pulp consists of nucleated cells (fig. 18, *p*), with capillary vessels and nerves invested by a structureless membrane, which disappears during the formation of the dentine. The superficial pulp-cells assume an elongated form as they approach the periphery; and after the formation of the tooth has commenced, their nuclei correspond in diameter and direction with the tubes of the contiguous cap of dentine. The cells are observed in a state of transition into dentine in the interspace between the pulp and the previously formed cap of dentine: they adhere to the latter when it is displaced from the pulp.

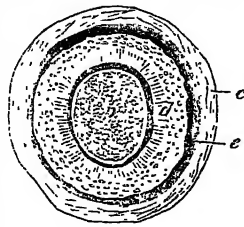

Fig. 18.
Section of the Matrix of the Pulp
of a Human Tooth.

Observations on the pulp in its various stages of conversion into dentine, whilst in undisturbed connection with the calcified portion in the thin transparent lamelliform teeth of a foetal shark (*Carcharias*), first yielded unequivocal demonstration of the organic continuity of the cap of dentine with the supporting vascular pulp; they also indicated some stages of the progress of the conversion of the pulp into dentine, and produced that clear idea of the nature and relations of dental development which is expressed (as previously quoted) in the *Theory of Dentification by Centripetal Calcification of the Pulp's Substance*, submitted to the French Academy in December 1839.¹ The following are the progressive steps of the calcifying processes, according to the writer's microscopic researches on the formation of the different substances which compose the more complex teeth of reptiles and mammals, as pursued in various species of both classes, but chiefly in the higher organized domestic animals:—

Three formative organs are developed, as already described, for the three principal or normal dental tissues. The dentinal pulp (figs. 16 and 18, *p* and *d*), or pulp proper, for the dentine; the "capsule" (figs. 16 and 18, *c*), for the cement; and the enamel-pulp (figs. 16 and 18, *e*), for the enamel. The essential fundamental structure of each formative organ is cellular; but the cells differ in each organ, and derive their specific character from the properties and metamorphoses of their nucleus, upon which the specific microscopical character of the resulting calcified substances depend. In the cells of the dentinal pulp the nucleus fills the parent cell with a progeny of nucleoli before the work of calcification begins; in the enamel-pulp the nucleus of the cell disappears, like the cytotblast of the embryo plant in the formation of most vegetable tissues; in the cells of the capsule the nucleus neither perishes nor propagates, but retains its individuality, and gives origin to the most characteristic feature of the cement,—viz., the radiated cell. The primordial material of each constituent of the tooth-matrix is derived from the blood, and special arrangements of the blood-vessels pre-exist to the development and growth of the constituent substances. A pencil of capillaries is directed to a particular spot in the primitive dentiparous groove, and terminates there by a looped net-work, from which spot a group of nucleated cells begin to arise in the form of a papilla. The cells of the papilla are, however, colourless, and the plexus of capillaries is confined to its base.

In the Mammalia (embryo calf of 3 inches in length)

membranous septa are formed, into which the vessels extend, which septa cross the groove and inclose the papilla in a follicle; the epithelial gum closing in the follicle is shown at *f*, fig. 16. From the free margin of this follicle the processes are developed which indicate the configuration of the future crown of the tooth, and in the molars of the calf subsequently develop the re-entering folds on which the complex structure of the crown of the molar tooth depends. The primary dentinal papilla and its capsule rapidly increase by successive additions of nucleated cells, apparently derived by material supplied by the capillary plexus at the base; the capillaries now begin to penetrate the substance of the pulp itself, where they present a sub-parallel or slightly diverging penicillate arrangement, but preserve their looped and reticulate termination near the apex of the pulp. Fine branches of nerves accompany the capillaries, and terminate also in loops. The primary cells and the capillary vessels and nerves are imbedded in, and supported by, a homogeneous, minutely sub-angular mucilaginous substance, the "blastema." The cells which are smallest at the base of the pulp, and have large, simple, sub-angular nuclei, soon fall into linear series directed towards the periphery of the pulp; where the cells are in close proximity with that periphery, they become more closely aggregated, increase in size, and present the following changes in their interior:—A pellucid point appears in the centre of the nucleus, which increases in size, and becomes more opaque around that central point, rendering the compressorium requisite for its demonstration. A division of the nucleus in the course of its long axis is next observed, in the larger and more elongated cells, still nearer the periphery of the pulp, and to the field of calcification. The sub-divided and elongated nuclei become attached by their extremities to the corresponding nuclei of the cells in advance, and the attached extremities become confluent. Whilst these changes are proceeding, the calcareous salts of the surrounding plasma begin to be accumulated in the interior of the cells, and to be aggregated in a semitransparent state around the central granular part of the elongated nuclei, which now present the character of secondary cells (fig. 19, *d*), and the salts occupy, in a still clearer and more compact state, the interspaces *c* of such cells; the elongated granular matter of the terminally confluent secondary cells establishes the area of the tubes *d*, by resisting, as it would seem, the encroachments of the calcareous salts, the nuclear tracts receiving a smaller proportion of the salts in the condition of minute disgregated particles, which are usually arranged in a linear series of nodules, and contribute to cause the white colour of the

newly-calculated Dentinal Pulp
(Calf).

opacity when viewed by transmitted light. Thus the primitive existence of the granular nuclei, their multiplication in the primary or parent cell, their elongated form, their serial arrangement end to end, and terminal confluence, are indicated in the calcified pulp by the area of the dentinal tubes (fig. 19, *d*); the interspaces of the metamorphosed nuclei being occupied by calcareous salts in a clearer and more compact state *c*, with evidence, however, of a distinctness of nucleolar membrane or secondary cell from the cavity of the common containing cell, which sustains the

Introduction.

¹ The general results of this communication were given in the *Comptes Rendus*, 1839, p. 783. The commission appointed by the French Academy to report on a subsequent memoir on the same subject, advert to some of the phenomena previously communicated by the present writer. "Quant aux préparations qui montrent l'aréolite de la pulpe, non seulement nous les avons reproduites avec succès; mais de plus nous avons constaté, à l'état frais, la granulation des aréoles signalée par M. Richard Owen," *loc. cit.* 1842, p. 1063.

Intro-
duc-
tion.

interpretation of the "proper parietes" of the dentinal tube. The indications of the primitive boundary or proper parietes of the parent cell (fig. 19, *a*) are in like manner more or less distinctly retained, through a modification of the arrangement of the calcareous salts in the boundaries and in the interspaces of the cells. The salts are sometimes blended with the blastema in these interspaces in a disgregated condition, which renders them almost as opaque as the area of the tubes. When a layer of the calcified cells is carefully detached, the exposed uncalcified surface of the pulp presents the appearance of a net-work, the meshes being formed by the exposed cells and the intervening very thin layer of blastema. Each mesh, however, which gives a transparent or bright contour to the cell, when viewed by transmitted light, instead of presenting a single stellate nucleus, shows, by well-directed light under a higher power, several points, each of which have been torn from the cavities of the dentinal tubes in the displaced cap of dentine. A view of the thin transparent margin of the cap of a growing tooth, which may be cut off with a pair of fine scissors, easily affords the means of demonstrating the corresponding structure in that calcified part of the pulp. A slight change of focus is required to bring the ends of the tubuli in view, from that in which the clear outline of the dentinal cell is best seen. In proportion as the process of calcification approximates the cells, and as these have undergone the changes in their nucleolar contents preparatory to the proper arrangement of the hardening salts within, the proportion of the basal substance in the interspaces of the cells to the enlarged cells themselves decreases, and the cells become more readily detached, and seemingly independent, when torn out in the displacement of the cap of dentine. Although they are less adherent laterally to the basal substance of the pulp, they are more coherent with the cells of the same linear series, the tubes of the calcified cell accepting or effecting a union with the peripheral ends of the elongated granular nuclei, or nucleolar cavities of the contiguous cell in the next central layer. The angles at which the elongated nuclei, or successive portions of the dentinal tubuli, thus unite, constitute the secondary gyrations or curves of the cells. The primary curves depend upon the arrangement of the primary linear series of the parent cells or compartments of the pulp.

The original contour of these cells is most discernible after calcification of the teeth of the Mammalian class, and here with different degrees of distinctness in different species. They are the true dentinal cells or compartments (fig. 3, *a, a*), and must not be confounded with the so-called intertubular or interfibrillar cells *f, g*, the first notice of which is due to Retzius. The diameter of the dentinal compartments or calcified primary cells of the pulp is usually one-fourth or one-half larger than that of the blood-disc of the species manifesting them. These cells are figured in the treatise on *Odontography* above referred to, in the *Myiodon* (pl. 79), in the incisive tusk of the *Dugong* (pl. 95), in the premolar (pl. 113), and in the canine (pl. 113, *a*) of the *Pteropus*, in the incisor of the chimpanzee (pl. 119, *a*), and of the human subject (pl. 123), and in the molar of a rhinoceros (pl. 139). They have been subsequently described and figured by Czermak.¹

The altered mode of action, or change in the nuclei of the smaller central cells of the pulp, is the first and essential step in the modification of the dentinal tissue which produces the substances which are termed osteodentine and vasodentine. In the former, many of the cells retain their nucleus undivided, and the hardened salts are impacted around it in the interior of the cell, but enter only partially into the granular substance of the nucleus, in the minutely disgregated form, which produces the opacity and whiteness

of the resulting corpuscle. In the formation of vasodentine many of the cells lose their nucleus, which seems to have become dissolved. In both the latter modifications of dental tissue the blood-vessels remain, and establish the wide tubular tracts in the calcified substance to which the name of the "vascular canals" is given. In true, hard, or unvascular dentine no trace of the blood-vessels remains; all has been converted into a much more minute calcified tubular tissue by the assimilative or intersusceptive properties of cells, and by the modification of their nucleolar contents. But the vascularity of the dentinal pulp, and especially the rich network of looped capillaries that adorns the formative peripheral layer at the period of its functional activity, have attracted general notice, and have been described by Hunter and subsequent authors on dental development. By most this phenomenon has been regarded as evidence of the secreting function of the surface of the pulp, and the dentine as an out-pouring from that vascular surface which was supposed to shrink or withdraw from the matter excreted. For it has been asked, "If the unvascular dentine be the effect of the conversion of the vascular pulp, by what process is all trace of the vascular ramifications obliterated, since none can be detected in such dentine?" The same question is equally applicable to the nerves of the pulp. In the explanation of this process attention must first be paid to the almost straight and sub-parallel course of the vessel in the pulp's substance, and to the remarkable regularity of form and size of the meshes of the terminal reticulation on the surface of the pulp.

At the part where calcification has commenced the extremities of the capillaries are commonly found in a state of congestion, and crowded with blood-discs, which are pressed together into polyhedrons, and apparently stagnated and left out of the current of circulation. These aggregated blood-discs exhibited, in various and often in striking degrees, those changes of the contained matter to which their own multiplication may be due. In this present situation and condition it is obvious that such changes must be preparatory either to their disappearance and removal, or to some important share which they are destined to take in the development of the dental tissue. The stagnant corpuscles nearest the vascular and unchanged pulp exhibit the irregularity of contour which has given rise to the terms "mulberry" or "granulated," applied to such altered blood-discs when seen in other circumstances. These corpuscles in other respects, as colour, size, and general form, retained their usual character. The blood-discs nearer the cap of dentine exhibited more plainly the contained granules, to the commencing development of which the irregular contour above mentioned is due; this appearance was associated with an increase of size, a change from the circular to the elliptical form, and a gradual loss of the characteristic colour, which was longest retained by the central granular matter.

The enamel-pulp differs from the dentinal pulp at its first formation by the more fluid state of its blastema, and by the fewer and more minute cells which it contains. The part of the blastema next the dental pulp acquires more consistence by an increased number of its granules, and it contains more numerous and larger cells. Many of these show a nuclear spot, others a nucleus and nucleolus; the spherical nucleolar cells in the part of the blastema farther from the capsule are so numerous as to form an aggregate mass, with a small quantity of the condensed blastema in the minute interspaces left between the cells, which are pressed together into hexagonal or polygonal forms. In this state they constitute a great part of the enamel-pulp, which is of considerable extent in the complex molar teeth of the ruminants. The appearance produced by these

tion.

aggregate cells, in a section of the tooth-matrix of a calf's molar, is compared by Raschkow¹ and Purkinjé to the actinenchyma of certain vegetable tissues, and the connecting condensed blastema to threads of cellular tissue. The field of the final metamorphosis of the cells into the moulds for the reception of the solidifying salts is confined to close contiguity with the surface of the dentinal pulp. Here the cells increase in length, lose all trace of their nucleus, and become converted into long and slender cylinders, usually pointed at both ends, and pressed by mutual contact into a prismatic form. These cylinders have the property of imbibing the calcareous salts of the enamel from the plasmatic fluid, and of compacting them in a clear and almost crystalline state in their interior—the disappearance of the nucleus being evidently the condition of the absence of any permanent cavity, cell, canal, or other modification of the mineral matter, at least in the enamel-fibres of the calf. In the human subject it is probable that the cavity of the cylinder may be subdivided, by a multiplication of delicate nucleoli, into compartments; or that the remains of such multiplied nucleoli may cause a modification of the walls of the cylinder, and so produce the characteristic transverse striæ of the enamel-fibre. This appearance is not presented in the enamel of the frog's tooth, nor in that of the teeth of the hog or calf, in which animals the writer's observations of the development of this tissue have been chiefly made. As the development proceeds, the cells in immediate contiguity with the calcified prisms undergo the same changes as their predecessors, and become united to them by their peripheral pointed extremities; whilst the fluid plasmatic contents of the cells are exchanged for the dense salts of which the enamel is chiefly composed. The selective surface formed by the organic membrane of the cell would seem to be destroyed by the very pressure resulting from its own action, and exerted by the contents of the closely-packed contiguous prisms when the cavities of the cells are completely filled. The membrane ceases, at least, to be distinguishable under the microscope from the solid contents of the cell, except at that surface of the enamel next the capsule, and which is still in progress of growth. What is remarkable here is, that not the whole of the actinenchymatous part of the enamel-pulp is converted into the long and slender prismatic cellular basis of the enamel; at least in the valleys of the complex crown of the molars of the ruminant and pachyderm (calf and colt). This part of the enamel-pulp originally occupies more space than the subsequent layer of enamel does; and this superfluous peripheral part seems to be absorbed, and its place to be occupied by a growth or thickening of the vascular capsule. No capillaries pass from the capsule into the actinenchymatous pulp of the enamel; nor has the writer been able to trace a blood-vessel into that part of the capsule which was actually the seat of the calcifying processes. Here, as in the dentinal and enamel pulps, the calcareous salts are selected and arranged by the assimilative, selective, and intus-susceptive properties of the cell walls, and by the repellent power of their nuclei. The enamel pulp bears a relation to the dentinal pulp analogous to that which the peripheral part of the matrix producing the vitrodentine of the shark's tooth bears to the body of the matrix forming the osteodentine. Evidence of the close connection between the enamel and dentine in the marsupial Mammals is given in plate 102 of the author's *Odontography*. The differentiation of the two tissues, and the distinction of their formative pulps, become greater in the higher Mammalia.

The blastema or fundamental tissue of the capsule is at first semitransparent, and of a pearly or opaline colour, but

Introduc-
tion.

richly ornamented with blood-vessels. As the period of its calcification approaches, which is later than that of the dentinal pulp, it becomes denser, and exhibits numerous nucleated cells. The blastema itself presents more evidently a fine cellular or granular structure, in which the calcareous salts are impacted in a comparatively clear state, constituting the framework of the cemental tissue. The characteristic features of this tissue are due to the action of the proper nucleated cells upon the salts of the plasma diffused through the blastema, in which those cells are imbedded—the cells being characterized by a single large granular nucleus, which almost fills the clear area of the cell itself. If, when the formation of the cement has begun in the incisor or molar of a colt, one of the detached specks of that substance, with the surrounding and adhering part of the inner surface of the capsule in which it is imbedded, be examined, these nucleated cells are seen closely aggregated around the calcified part in concentric rows, the cells of which are farther apart as the rows recede from the field of calcification. Those next the cement rest in cup-shaped cavities in the periphery of the calcified part; just as the first calcified cells of the thick cement which covers the crown of a complex molar are lodged in the exterior of the enamel. These exterior cavities of the cement are formed by centrifugal extension of the calcifying process in the blastema in which the cells are imbedded. The calcareous salts penetrate, in a clearer and more compact state, the cavity of the cell; but their progress is arrested apparently by the nucleus, which maintains an irregular area, partly occupied by the salts in a subgranular, opaque condition, but chiefly concerned in the reception and transit of the plasmatic fluid, which enters and escapes by the minute tubes which are subsequently developed from the nucleolar cavity as calcification proceeds. The radiated cells or cavities thus formed are the most common characteristic of the cement, but not the constant one. The layer of the capsule which surrounds the crown of the human teeth, and of the simple teeth of *Quadrumanæ* and *Carnivora*, consists of the granular blastema, without or with very few nucleated cells; and the radiated corpuscles are consequently not developed, or are sparingly developed, in the cement which results from its calcification. In the thicker parts of the inflected folds of the capsule of the complex teeth of the *Herbivora*, traces of the vascularity of that part of the matrix are persistent, the blastema calcifying around certain of the capillaries, and forming the medullary canals. The parietes of these canals are traversed by minute tubes, continued from, or communicating with, the radiated cells.

In the deep sockets of the teeth of persistent growth the matrix is maintained by the constant additions of new blastema and cell material to the bases of the dentinal, enamel, and cemental pulps. The author has demonstrated the partial growth of the enamel-pulp along the side of the capsule corresponding to the convexity of the long incisor of the under-jaw of the porcupine, in the preparation now in the physiological series of the Hunterian collection (No. 375 A.)

Chemical analyses² of the composite substances, as built up by the organizing processes in the fundamental tissues of the matrix above described, have yielded the following teeth results:—

The proportion of mineral or inorganic substance would seem to vary, within certain limits, in different individuals of the same species. Thus, in the molar teeth of one man Bibra found 79.00 of inorganic matter, and in another, 71.99; whilst Berzelius found 72.0. The proportion of inorganic matter in hard dentine will depend in some degree upon the number of dentinal tubes, from the area of which the salts are in part excluded: thus, in the modified dentine (ivory) of the elephant's tusk, in which the tubuli are more numerous, close-set, and extensively undulated in a given space than in ordinary dentine, the organic bears a greater proportion to the inorganic matter than in the dentine of the teeth of most other Mammals. The cement of the composite molar teeth of the ruminants and of the elephant contains a little more organic matter than the dentine does; but in the cetaceous dolphin it contains a rather less proportion, and is consequently harder.

The nerves of the teeth are derived from the trigeminal Nerves of or fifth pair, of which the second division supplies those of the teeth. the upper jaw, the third division those of the lower jaw (fig. 20). In the human subject, the three dental branches

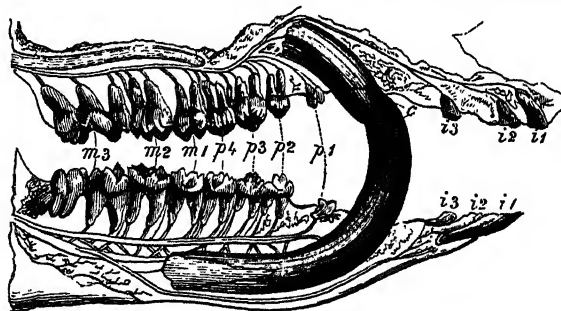

Fig. 20.

Upper and Lower Jaws of a Hog, dissected to show the Nerves of the Teeth.

of the infra-orbital nerve intercommunicate by their primary branches, from which, and from a rich plexus formed by secondary branches upon the membrane lining the antrum, two sets of nerves are sent off to the alveolar processes of the upper jaw: one set (*rami dentales*) supplies the teeth, the other (*rami gingivales*) the osseous tissue of the jaw and the gums. The latter agree in number with the intervals of the teeth, as the proper dental nerves do with the teeth themselves. These two sets are not, however, so distinct but that some intercommunications are established between the fine branches sent off in their progress to the parts they are specially destined to supply. The *rami dentales* take the more direct course through the middle part of the osseous tissue of the teeth, penetrate the orifices of the fangs, and form a rich plexus with rhomboidal meshes

Introduction. upon the coronal surface of the pulp, the peripheral elementary filaments returning into the plexus by loops.

In the lower jaw, the dental nerve, besides supplying the proper nerves to the teeth, also forms a rich plexus, in which it is joined by some branches from the division of the nerve that afterwards escapes by the *foramen mentale*, and from this plexus the cancellous tissue of the bone, as well as the gums, are supplied.

In the dog and other Carnivora the nerve of the laniary tooth is conspicuous from its size: that which supplies the still more developed analogous tooth or tusk of the boar (fig. 20, c) is still more developed, having relation also to the continual reproduction of the matrix at the base of the tusk. In the lower jaw of the porcupine (fig. 21) the nerve of the great incisor is given off from the dental nerve (n),

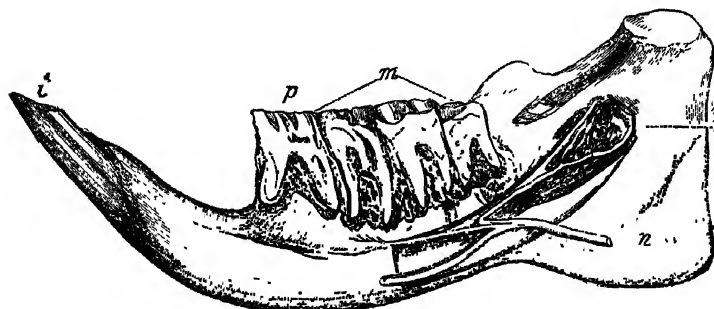

Fig. 21.

Lower Jaw of a Porcupine, dissected to show the Nerves of the Great Incisor, natural size.

near the middle of its course through the osseous canal, and returns at an acute angle to penetrate the cavity at the base of the scalpriform tooth, and supply its persistent pulp *z*. This recurrent course indicates the progressive change in the relative position of the pulp to the origin of its nerve.

Besides the branches for the molar teeth, many smaller filaments penetrate the spongy texture of the bone, and form a rich plexus, from which the gum derives its filaments. The maxillary plexus is most richly developed, in the horse, above and between the alveoli of the three pre-molar teeth; it is less complex where it supplies the molar teeth, their alveoli, and the gums. In the lower jaw of the horse a very rich plexus begins to be formed in the cancellous substance of the bone by branches of the dental nerve soon after its entry into the canal. The intercommunications between the dental and gingival nerves, and those supplied to the osseous tissue from the supra-maxillary and infra-maxillary plexuses, explain the sympathies manifested in neuralgia and rheumatic pains between the teeth and the osseous cavities in which they are implanted.

Histology of teeth.

The class of tissues in which teeth should rank has frequently been a subject of controversy in systems of histology; the fact being overlooked, that they have not the same unity of composition as bones or epidermal appendages. One constituent of teeth, viz., the cement, ought clearly to rank with the osseous tissue; and the dentine or ivory, which was described for the last time, probably, in July 1838, as being, "like the hair, arranged in concentric layers,"¹ bears, on the contrary, a close analogy to bone in structure, and is almost identical with it in chemical composition. Its modifications, called "vasodentine" and "osteodentine," form intermediate gradations between the hard dentine and true bone. True enamel is a tissue *per se*; but in the teeth of fishes there are several intermediate stages of gradation, which link enamel to dentine, as the dentine itself in most fishes passes gradually into bone. Heusinger² admits that the relation of the teeth to

the corneous tissue (*horngewebes*) is not clearly elucidated in human anatomy, but he affirms that it is most conclusively established in that of the lower classes of animals.

Introduction.

No doubt, in tracing the modifications of the dental system through the animal kingdom, we find true horny productions substituted for teeth in certain vertebrate species, as the Ornithorhynchus, whale, tortoise, &c. So likewise the office of teeth is performed by parts (modified as to form) of the crustaceous and chitinous integuments of the articulate classes; but there are no transitional or intermediate structures, such as Heusinger alludes to, between teeth and nails, horns or hair. The lamellar disposition traceable in the texture of the hardest dentine is much more closely similar to that of bone, especially the concentric plates surrounding the Haversian canals, than to the texture of nails. The structure of the tooth of *Orycteropus* is essentially like that of all true teeth: the apparent resemblance which it presents to the horn of the rhinoceros, or to baleen, arises from its being compounded of many minute parallel and elongated denticles. And the close resemblance in intimate structure and chemical composition between true teeth and bones being established, it may be observed that the osseous tissue is not confined to the endo-skeleton: it is developed largely to form the exo-skeleton in fishes, in the loricate reptiles, and even in the Mammalian class,—as, for example, in the armadillos, where bone is substituted, to strengthen the integument, for horn, which forms the scaled armour

of the allied pangolins. Now, the relation of the tooth of the armadillo to that of the Ornithorhynchus is precisely analogous to that which subsists between the osseous plates of the armadillo, and the corneous scales of the Manis; but this relation no more establishes identity of tissue or system of tissues in the one case than in the other.

The general form of the matrix or formative organ of teeth, and the relative position of the dental pulp to its product, bear a close analogy with those of the formative organ of hairs, bristles, shells, and other productions of the epidermal system. In these, however, the papilla or pulp is developed from the external skin; in the teeth from the mucous membrane or internal skin. Teeth further agree with the extra-vascular appendages of the skin in being shed and reproduced,—sometimes once,—sometimes frequently during the lifetime of the individual; the latter condition may be termed "interrupted reproduction." In some cases, again, as with certain epidermal productions, the reproduction of the tooth is "uninterrupted," and goes on continuously during the lifetime of the individuals, new matter being added to the base as the old is worn away from the apex or working surface of the tooth.

A tooth, when fully formed, is subject to decay, but has no inherent power of reparation. A tooth of limited growth can only increase in size after its formation is completed by abnormal growth of its most highly organized constituent, the cement. Thus the analogy of the dental organs to those of the corneous system holds only in their mode of development,³ in their shedding and reproduction, and in their exposure to external influences, and to the contact of extraneous bodies: but the antlers of deer are similarly exposed, and are likewise shed and reproduced annually, and also contemporaneously with the fall and reproduction of the hair; yet antlers are not therefore classed with the horny tissues, any more than the bony cone of the horns of the cavicorn ruminants.

¹ *Medico-Chirurgical Review*, p. 43.

² *System der Histologie*, 4to, 1823, p. 160.

³ The cells and fibres of the horny tissues are formed in, and not excreted from, the surface of their formative pulps.

SECT. I.—TEETH OF FISHES.

Teeth of
Fishes.

The fishes of Great Britain, and those which are known to us by vernacular names, form a comparatively small part of the class; but wherever the dentition of such is described, the species will be indicated in the present article by their common names. As, however, many interesting modifications of the dental organs occur in exotic fishes, known by no other names than those by which they are recorded in the systems and catalogues of naturalists, the information respecting their dentition which is here endeavoured to be given must be unavoidably confined to those who combine some knowledge of Zoology with that of Comparative Anatomy.

Excellent illustrations of the dental system in fishes are given in the article ICHTHYOLOGY, as, *e.g.*, from the predaceous *Alepisaurus* (p. 213, fig. 19), the phytiphagous *Ploctosus* (p. 220, fig. 50), and in various other species, from figs. 52 to 62 inclusive, accompanied with so exact a summary of the general modifications of the system in the piscine class, as leaves little to be added in the present article on that head. Yet this little appears necessary; for the teeth of fishes, whether we study them in regard to their number, form, substance, structure, situation, or mode of attachment, offer a greater and more striking series of varieties than do those of any other class of animals.

Number.

As to *number*, they range from zero to countless quantities. The lancelet, the ammocete, the sturgeon, the paddle-fish, and the whole order of *Lophobranchii*, are edentulous. The Myxinoids have a single pointed tooth on the roof of the mouth, and two serrated dental plates on the tongue. The tench has a single grinding tooth on the occiput, opposed to two dentiferous pharyngeal jaws below. In the lepidosiren (fig. 36), a single maxillary dental plate is opposed to a single mandibular one, and there are two small denticles on the nasal bone. In the extinct sharks with crushing teeth, called *Ceratodus* and *Ctenodus*, the jaws were armed with four teeth, two above and two below. In the *Chimæra* two mandibular teeth are opposed to four maxillary teeth. From this low point the number in different fishes is progressively multiplied, until in the pike and many other fishes the mouth becomes crowded with countless teeth.

Substance.

With reference to the main and fundamental tissue of tooth, we find not fewer than six leading modifications in fishes:—Hard or true dentine,—*Sparoids*, *Labroids* (fig. 6), *Lophius*, *Balistes*, *Pycnodonts*, *Prionodon*, *Sphyræna*, *Megalichthys*, *Rhizodus*, *Diodon*, *Scarus*: Osteo-dentine,—*Cestracion*, *Acrodus*, *Lepidosiren*, *Ctenodus*, *Hybodus*, *Percoids*, *Sciænoids*, *Cottoids*, *Gobioids*, and many others: Vaso-dentine,—*Lamna* (fig. 7), *Psammodus*, *Chimæroids*, *Pristis*, *Myliobates*: Plici-dentine,—*Lophius*, *Holoptychius*, *Lepidosteus oxyurus*, at the base of the teeth: Labyrintho-dentine,—*Lepidosteus platyrhinus*, *Bothriolepis*: and Dendro-dentine,—*Dendrodus* (fig. 14); besides the compound teeth of the *Scarus* and *Diodon*.

Structure.

One structural modification may prevail in some teeth, another in other teeth of the same fish; and two or more modifications may be present in the same tooth, arising from changes in the process of calcification and a persistency of portions or processes of the primitive vascular pulp or matrix of the dentine. The modifications of dentine, called vasodentine and osteodentine,¹ predominate much more than in the higher Vertebrata; and they thus more closely resemble the bones which support them. There is, however, great diversity in respect of substance. The teeth

of most of the Chætodonts are flexible, elastic, and composed of a yellowish subtransparent albuminous tissue; such, likewise, are the labial teeth of the Helostome, the premaxillary and mandibular teeth of the Goniodonts, and of that percoid genus thence called *Trichodon*. In the Cyclostomes (lampreys) the teeth consist of a denser albuminous substance. The upper pharyngeal molar of the carp consists of a peculiar brown and semitransparent tissue, hardened by salts of lime and magnesia. The teeth of the flying-fish (*Exocoetus*) and sucking-fish (*Remora*) consist of osteodentine. In many fishes, *e.g.*, the *Acanthurus*, *Sphyræna*, and certain sharks (*Lamna*, fig. 7), a base, or body of vasodentine, is coated by a layer of true dentine, but of unusual hardness, like enamel; in *Prionodon* this hard tissue predominates. In the *Labrus* the pharyngeal crushing teeth consist wholly of hard or unvascular dentine (fig. 6). In Pycnodonts, and many other fishes, the body of the tooth consists of ordinary unvascular dentine, covered by a modification of that tissue which I have called "vitro-dentine," from its clear, polished, enamel-like character; but this is not enamel, nor the product of a distinct organ from the dental pulp: it differs from ordinary dentine in the greater proportion of the mineral particles, their more minute diffusion through the gelatinous basis, and in the straighter course and more minute size of the dental tubes; it results from the calcification of the external layer of the dental pulp, and is the first part of the tooth which is formed. In *Sargus* and *Balistes* the body of the tooth consists of true dentine, and the crown is covered by a thick layer of a denser tissue, developed by a distinct organ, and differing from the "enamel" of higher animals only in the more complicated and organized mode of deposition of the earthy salts. The ossification of the capsule of the complex matrix of these teeth covers the enamel with a thin coating of "cement." In the pharyngeal teeth of the *Scarus* a fourth substance is added by the ossification of the base of the pulp after its summit and periphery have been converted into hard dentine; and the teeth thus composed of cement, enamel, dentine, and osteodentine, are the most complex, in regard to their substance, that have yet been discovered in the animal kingdom.

The tubes which convey the capillary vessels through the substance of the osteodentine and vasodentine of the teeth of fishes² were early recognised on account of their comparatively large size,—as by André, *e.g.*, in the teeth of *Acanthurus*, and by Cuvier and Von Born in the teeth of the wolf-fish and other species. Leeuwenhoek had also detected the much finer tubes of the peripheral dentine of the teeth of the haddock. These dental tubuli are given off from the parietes of the vascular canals, and bend, divide, and subdivide rapidly in the hard basis-tissue of the interspaces of those canals in osteodentine; the dental tubuli alone are found in true dentine, and they have a straighter and more parallel course, usually at right angles to the outer surface of the dentine. Those conical teeth of fishes which, when fully-formed, consist wholly or in great part of osteodentine or vasodentine, always first appear with an apex of hard or true dentine. In some fishes the simple central basal pulp-cavity of such teeth, instead of breaking up into irregular or parallel canals, sends out a series of vertical plates from its periphery, which, when calcified, give a fluted character to the base of the tooth, *e.g.*, in *Lepidosteus oxyurus*. Sometimes such radiating vertical basal plates of dentine are wavy in their course, and send off narrow processes from their sides; and as a thin layer of the outer capsule inter-

Teeth of
Fishes.

² The vasodentine of *Pristis* and *Myliobates* is like that of the teeth of the Cape ant-eater (*Orycteropus*); the vasodentine of the Psammodonts resembles that which forms the base of the tooth of the sloth and megatherium; the vasodentine of Mammals differs from the osteodentine, in the absence of the radiated "Purkingian" cells.

Teeth of
Fishes.

digitates with the outstanding plates of the dentinal pulp, and becomes co-calcified with them, a transverse section of such a tooth presents a series of interblended wavy or labyrinthic tracts of thick dentine radiating from the centre, and of thin cement converging towards the centre of the tooth.

An analogous but more complicated structure obtains, when the radiating wavy vertical plates of dentine dichotomize, and give off from their sides, throughout their course, numerous branch plates and processes, which are traversed by medullary sinuses and canals, with their peripheral terminations dilated, and becoming the centres of lobes or columns of hard dentine. The transverse section of such teeth gives the appearance of branches of a tree, with leaf-stalks and leaves radiating from the central pulp-cavity to the circumference of the tooth; whence the fossil fish in which this structure was first detected has been called *Dendrodus* (fig. 14).

Situation.

With respect to *situation* the teeth in sharks and rays are limited to the bones (maxillary and mandibular) which form the anterior aperture of the mouth. In the carp and other Cyprinoids the teeth are confined to the bones (pharyngeal and basi-occipital) which circumscribe the posterior aperture of the mouth. The wrasses (*Labrus*) and the parrot-fishes (*Scarus*) have teeth on the premaxillary and premandibular bones, as well as on the upper and lower pharyngeals; both the anterior and posterior apertures of the mouth being thus provided with instruments for seizing, dividing, or comminuting the food, the grinders being situated at the pharynx. In most fishes teeth are developed also in the intermediate parts of the oral cavity; as on the palatines, the vomer, the hyoid bones, the branchial arches; and, though less commonly, on the pterygoids, entopterygoids, the sphenoids, and even on the nasal bone (fig. 36, c). It is very rare to find teeth developed on the true superior maxillary bones; but the herring and salmon tribes, some of the ganoid fishes, and the great *Sudis*, are examples of this approach to the higher Vertebrates. Among the anomalous positions of teeth may be cited, besides the occipital alveolus of the carp,¹ the marginal alveoli of the prolonged, depressed, well-ossified rostrum of the saw-fish (*Pristis*). In the lampreys, and in *Helostomus* (an osseous fish), most of the teeth are attached to the lips. Lastly, it is peculiar to the class *Pisces*, amongst Vertebrata, to offer examples of teeth developed in the median line of the mouth, as in the palate of the Myxines; or crossing the symphysis of the jaw, as in *Notidanus*, *Scymnus*, and *Myliobates*.

Attach-
ment.

Nor is the mode less varied than the place of *attachment*. The teeth of *Lophius*, *Pæcilia*, and *Anableps* are always moveable; in most fishes they are ankylosed to the jaw by continuous ossification from the base of the dental pulp, the histological transition being more or less gradual from the structure of the tooth to that of the bone. Sometimes we find, not the base, but one side of the tooth ankylosed to the alveolar border of the jaw, and the teeth oppose each other by their sides instead of their summits (*Scarus*); in *Pimelodus*, however, where the teeth are thus attached, the crown is bent down in the upper teeth, and is bent up in the lower ones, at right angles to the fang, so that they oppose each other in the normal way. Certain teeth of recent or fossil cartilaginous fishes have their base divided into processes like fangs; but these serve for the attachment of ligaments, and are not set in bony sockets like the true fangs or roots of the teeth of Mammals. Some sharks have two divaricating fangs. Some fossil teeth, referred to the genus *Petalodus* by Agassiz, with the specific name "*radicans*," have the base divided into several fangs or processes, indicating a generic distinction. The base of ankylosed teeth is at first attached to the jaw-bone by

ligament; and in the cod-fish, wolf-fish, and some other species, as calcification of the tooth progresses towards its base, the subjacent portion of the jaw-bone receives a stimulus, and develops a process corresponding in size and form with the base of the tooth. For some time a thin layer of ligamentous substance intervenes, but ankylosis usually takes place to a greater or less extent before the tooth is shed. Most of the teeth of the *Lophius* retain the primitive ligamentous connection. The ligaments of the large internal or posterior teeth of the upper and lower jaws radiate on the corresponding sides of the bones, the base of the tooth resting on a conformable alveolar process.

Some implanted teeth in the present class have their hollow base further supported, like the claws of the feline tribe, upon a bony process arising from the base of the socket; the incisors of the file-fish (*Balistes*, fig. 22), e.g., afford an example of this double or reciprocal gomphosis.

In fig. 22 the teeth in place, and the outer wall of the premaxillary, have been removed to show, as at *a*, the socket and the basal peg of the fully developed incisor; at *b* the apex of a successional incisor, which has worn away the peg, and caused the fall of the incisor it was about to succeed;

and at *c* the less advanced germ of the tooth destined to succeed that which was supported by the peg *a*.

The vertical section of a pharyngeal jaw and teeth of the wrasse (*Labrus*, figs. 23 and 6), would afford the architect a model of a dome of unusual strength, and so supported as to

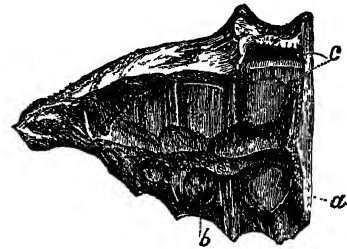

Fig. 22.

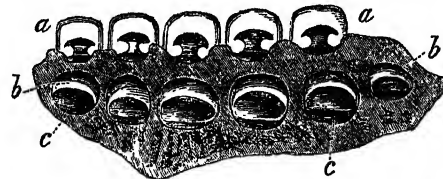

File-Fish (*Balistes forcipatus*).

Fig. 23.

Section of Pharyngeal Bone and Teeth of a Wrasse (*Labrus*).

relieve from pressure the floor of a vaulted chamber (fig. 23, *c*, *c*) beneath. The base of the dome-shaped tooth *a* is slightly contracted, and is implanted in a shallow circular cavity, the rounded margin of which is adapted to a circular groove in the contracted part of the base; the margin of the tooth, which immediately transmits the pressure of the bone, is strengthened by an inwardly projecting convex ridge. The masonry of this inner buttress, and of the dome itself, is composed of hollow columns, every one of which is placed so as best to resist or transmit in the due direction the external pressure (fig. 23). The floor of the alveolus is thus relieved from the office of sustaining the tooth: it forms, in fact, the roof of a lower vault, in which the germ of a successional tooth (fig. 23, *b*, *b*) is in course of development. Had the crushing tooth in use rested, as in the wolf-fish, by the whole of its base upon the alveolus, the supporting plate, gradually undermined by the growth of the new tooth, must have given way, and been forced upon the subjacent delicate and highly vascular and sensitive matrix of the half-formed tooth. But the superincumbent pressure is exclusively sustained by the border of the alveolus, whence it is transferred to the walls dividing the vaulted cavities containing the germs of the new teeth.

¹ *Odontography*, pl. 8, vol. iii., p. 980, fig. 518.

Teeth of
Fishes.

The roofs of these cavities yield to the absorbent process consequent on the growth of the new teeth, without materially weakening the attachment of the old teeth, and without the new teeth being subjected to any pressure until their growth is sufficiently advanced to enable them to bear it with safety. By this time the sustaining borders of the old alveolus are undermined, and the worn-down tooth is shed.

Many analogous structures could be adduced did space permit: in fact, the whole of this part of the organization of fishes is replete with beautiful instances of design, and instructive illustrations of animal mechanics.

Develop-
ment.

As might have been anticipated from the discovery of the varied and predominating vascular organization in the teeth of fishes, and the passage from non-vascular dentine to vascular dentine in the same tooth, the true law of the development of dentine "by centripetal metamorphosis and calcification of the cells of the pulp," was first definitely enunciated and illustrated from observations made on the development of the teeth of fishes.¹

It is interesting to observe in this class the process arrested at each of the well-marked stages through which the development of a mammalian tooth passes. In all fishes the first step is the simple production of a soft vascular papilla from the free surface of the buccal membrane. In sharks (fig. 24) and rays, these papillæ do not proceed to sink into the substance of the gum, but are covered by caps of an opposite free fold of the buccal membrane. These caps *f, g*, do not contract any organic connection with the papilliform matrix; but, as this is converted into dental tissue, the tooth is gradually withdrawn from the extraneous protecting cap to take its place and assume the erect position on the margin of the jaw, as at *a, b*. Here, therefore, is represented the first and transitory "papillary" stage of dental development in Mammals; and the simple crescentic cartilaginous maxillary plate, with the open groove behind containing the germinal papillæ of the teeth, offers in the shark a magnified representation of the earliest condition of the jaws and teeth in the human embryo.

In many fishes, *e.g.*, the angler (*Lophius*) and pike, the dental papillæ become buried in the membrane from which they rise, and the surface to which their basis is attached becomes the bottom of a closed sac; but this sac does not become inclosed in the substance of the jaw; so that teeth at different stages of growth are brought away with the thick and soft gum, when it is stripped from the jaw-bone. The final fixation of teeth so formed is effected by the development of ligamentous fibres in the sub-mucous tissue between the jaw and the base of the tooth; which fibres become the medium of connection between those parts, either

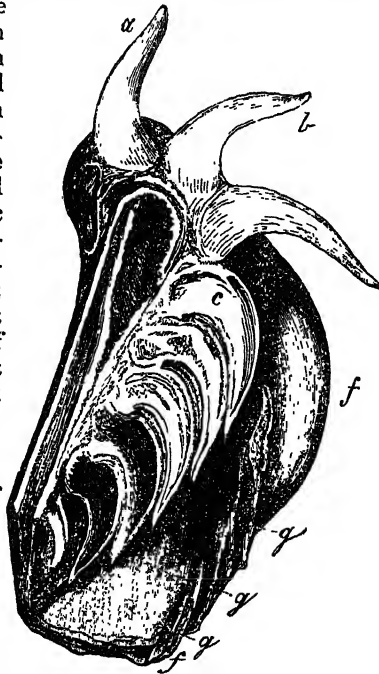

Fig. 24.

Section of the Jaw and Teeth of a Shark (*Lamna*). become the medium of connection between those parts, either

as elastic ligaments, or by continuous ossification. Here, therefore, is represented the "follicular" stage of the development of a mammalian tooth; but the "eruptive" stage takes place without previous inclosure of the follicle and matrix in the substance of the jaw-bone.

In *Balistes* (fig. 22), *Scarus* (fig. 34), *Sphyræna*, the Sparoids, and many other fishes, the formation of the teeth presents all the usual stages which have been observed to succeed each other in the dentition of the higher Vertebrata: the papilla sinks into a follicle, becomes surrounded by a capsule, and is then included within a closed alveolus of the growing jaw (fig. 22, *c*), where the development of the tooth takes place, and is followed by the usual eruptive stages. A distinct enamel-pulp is developed in *Balistes*, *Scarus*, *Sargus*, and *Chrysophrys*.

No cartilaginous fish has teeth implanted in maxillary alveolar cavities, or confluent with the substance of the jaw; they are attached to the fibrous and mucous membrane which cover the maxillary cartilages; thence it occurs, in certain genera, as *Myliobates* and *Scymnus*, that a single tooth in the median plane may lie directly across the symphysis, and be supported by the two rami of the jaw. The Plagiostomes, like many other natural families of fishes, present such modifications of their common and characteristic type of structure as fit them for very different habits of life, and the acquisition of different kinds of food. The active and predatory sharks are associated in this order with the sluggish omnivorous rays, and the dental system presents every grade of modification from the laniary to the molar type. The *Lamna* (fig. 24), with its teeth exclusively adapted for holding, piercing, and lacerating, and the *Myliobates* (fig. 26), with its maxillary mosaic pavement of flattened molars, form the two extremes of the series.

The sharks, or *squaloid* Plagiostomes, with few exceptions, have teeth of a conical, sharp-pointed, more or less compressed form, sometimes with trenchant or serrate edges and accessory basal denticles; they are arranged along the margin and posterior surface of the jaws in close-set vertical rows of from three to thirteen teeth in each row, according to the species. The teeth of the contiguous rows in certain genera, as *Selache* and *Lamna*, are parallel to each other; but in *Galeus* and *Carcharias* they are placed alternately, so that the base of one tooth advances laterally into the interspace of two teeth of the contiguous row, and reciprocally; but the laterally contiguous teeth are never articulated with each other, as in certain rays.

In general the anterior or external tooth only of each row is erect, the rest being recumbent. In *Lamna*, however, the second and third teeth are commonly seen in positions intermediate between those of the erect anterior (fig. 24, *a*) and the recumbent posterior teeth (*c*). It is scarcely necessary to repeat, that although the teeth of the sharks possess greater individual mobility than those of the rays, the recumbent ones (fig. 24, *c*) cannot, as has been supposed, be voluntarily erected. These teeth are still in progress of development, and several of them are covered by a reflection of the mucous membrane of the mouth (fig. 24, *g*), which would be lacerated by such a movement; it is by a gradual change of position in the fibrous membrane, to which their base is attached, that the altered direction of the consolidated teeth is effected.

The formation of the teeth of the sharks, as of many other fishes, exemplifies, on a large scale, the earliest or papillary stage of dental development in the higher classes of animals. It is not succeeded here by either a follicular or an eruptive stage; the formative papillæ are never inclosed, and consequently never break forth. The pulp, when consolidated by the deposition of the calcareous salts in the pre-existing cells and tubes, is gradually withdrawn from the protective sheath (fig. 24, *g*), which the thecal fold of mucous membrane *f, f* afforded during the early stages of its formation. In the uterine fœtus, one foot long, of the great white shark (*Charcharodon*), the jaws seem at first sight to be edentulous; a fissure presents itself on the inner side of the margin of each jaw, running parallel with it, between the thin smooth membrane covering the convex edge of the cartilage, and the free margin of a fold of mucous membrane which lies parallel to and upon the inner side of the jaw. When this fold is drawn away from the jaw, the minute teeth are exposed, arranged in the usual vertical rows; these points are all directed backwards and towards the base of the jaw, and are seen to slip out of fossæ or sheaths in the membranous folds, as this is gradually reflected backwards and

Teeth of
Fishes.

Teeth of
Fishes.

towards the base of the jaw. Here the anterior lamina of the fold, which, from its office, may be termed "thecal," is continuous with the mucous membrane at the base of the rows of teeth; the posterior layer is reflected backwards to the front line of attachment of the tongue. Close to the anterior line of reflection there is a row of simple conical papillæ; in the succeeding row the papillæ are larger, the cone broader and flatter, and its apex is covered with a small cap of dense and glistening dental substance, which is readily removed, though not without displacement of part of the dental pulp, the granules of which, adherent to the cavity of the displaced dental cap, are always readily recognisable under the microscope. The third series of papillæ, counting from below in the lower jaw, have acquired the size and shape of the future tooth, with the crenate edges well marked; half the tooth is completed, and its removal from the fleshy base of the pulp cannot be effected without evident laceration of the pulp. When this is done under the microscope, the torn processes of the pulp continued into the medullary canals of the new-formed tooth are plainly visible. The fourth tooth is completely formed, as also the fifth and sixth in the ascending series: these progressively diminish in size. The last or highest, which is first exposed on reflecting the thecal fold, and the first which was completed in the order of development, consists of a simple cone, similar in form and size to the apical third of the ordinary-sized teeth below it; yet its growth is quite completed, and its base firmly attached to the maxillary membrane.

In a fœtus of a white shark (*Carcharias ferox*) 3 inches long, which had not lost its external branchiæ, the membranous groove between the jaw and thecal fold was much shallower, and only two rows of papillæ were present on the maxillary membrane. The minute anterior teeth in the more advanced fœtus were developed from these primitive papillæ, which must be succeeded by others of progressively larger size, till the normal form and dimensions of the adult teeth are attained. The foetal shark is peculiarly favourable for such comparisons, as it presents numerous pulps and teeth in every stage of formation, easily detached, and without violence, from their exposed situation, and of a flattened form, well adapted for microscopical observation.

The unossified pulps, examined with a high power, consist of semi-opaque polyhedral granules or cells suspended in a clear matrix, and the whole is inclosed in a tough transparent membrane, which forms the outer surface of the pulp. Beneath this membrane, at the crenate margins, the nucleated cells are arranged in lines precisely corresponding with those of the subsequent dentinal tubes. The formation of the tooth commences by the deposition of earthy particles in the tough external membrane of the pulp. The present writer has been unable to recognise the distinct arrangement of the hardening salts in this layer. It is transparent, extremely dense, and forms the enamel-like polished coating of the tooth; in sections of fully-formed teeth, the finest terminal branches of the parallel peripheral dentinal tubes are lost in the above clear enamel-like substance. When this outer layer of the apex of the tooth is completed, it is so easily detached from the subjacent pulp, that it might be readily supposed that there was no organic connection between them. If, however, the so exposed pulp be now examined with the microscope, and compared with an uncalcified pulp, it is seen to be no longer covered with the smooth, dense membrane observable in the latter; but the apical edges, from which the enamel-like cap has been detached, appear villous or floccular. It is obvious that the first shell of the tooth has been neither transuded from the superficies of the external membrane of the pulp, nor has been deposited between that membrane and the granular part of the pulp, but is due to the conversion of the external membrane into a dense enamel-like bone. The formation of the body of the tooth by deposition of earthy particles in pre-existing and pre-arranged cavities is still more satisfactorily demonstrable. In proportion as the formation of the tooth has advanced, the difficulty of separating the calcified from the uncalcified portion of the pulp is increased; and at the same time it becomes easier to detect the continuation of the processes of the pulp into those medullary canals which form so many separate centres of radiation of the plexiform dentinal tubes.

As a consequence of a formation of a tooth by conversion of, instead of transudation from, a pre-existing pulp, the successive formation of these pulps necessarily follows where a succession of teeth is required. These reproductive pulps are developed, in the shark, from the vascular mucous membrane at the angle of reflection of the thecal fold upon the groove of the basal line of the jaws. They gradually advance from this situation towards the margin of the jaw, the centripetal calcification extends as they advance, and consolidation is completed (as in fig. 24, c) by the time the teeth are ready to change their recumbent for the erect position *ba*, and take the place of the tooth previously shed.

Teeth of
Fishes.

Raiidæ, or
Rays.

The teeth of the rays are in general more numerous than those of the sharks; they have less mobility, are more closely impacted, and in some cases are laterally united together by fine sutures, so as to form a kind of mosaic pavement on both the upper and lower jaws. The *Myliobates*, or eagle-rays, which present the last-mentioned condition, unique in the vertebrate sub-kingdom, have large and massive teeth (fig. 26); but in the rest of the present family of cartilaginous fishes, the teeth (fig. 25) are remarkable for their small size as compared with those of the sharks. The teeth in some species of rays are adapted for crushing, but in others they have the middle or one of the angles of the crown produced into a sharp point. In all genera of the ray tribe, whatever the diversity of size and shape of the teeth, they are placed in several rows, and succeed each other uninterruptedly from behind.

In the genus *Rhina*, each tooth is supported on a short fang or pivot, which tapers as it recedes from the crown; there is a groove along the posterior part of the pivot, and a perforation on each side; the crown is lozenge-shaped, convex above, and sculptured with a series of transverse and slightly undulating and punctate ridges, presenting a pattern which somewhat resembles that of the grinding surface of the comparatively gigantic tooth of the extinct cartilaginous fish of the chalk formation called *Psychodus*. The modification of the dentigerous surface of the jaws, and the beautiful quincuncial arrangement of these teeth, are exhibited in fig. 25.

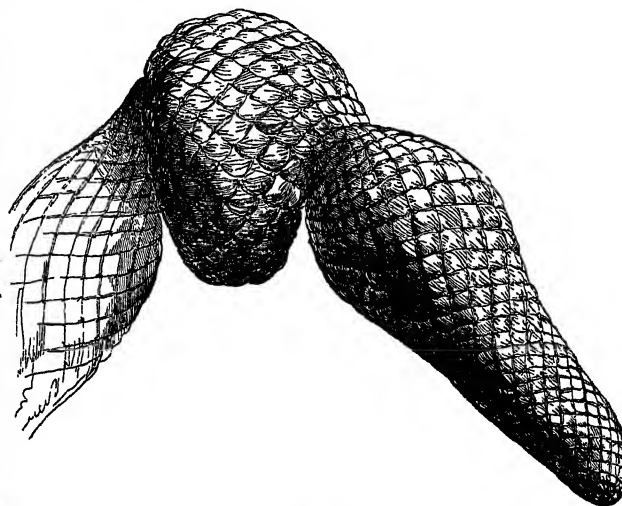

Fig. 25.
Dental Pavement of the Upper Jaw (*Rhina*).

The middle part of the upper jaw forms a bold prominent convexity, separated by a depression on each side from a lateral and less produced rising. The contour of the dentigerous surface of the lower jaw presents depressions corresponding to the eminences above, and *vice versa*.

The modification of the plagiostomous type of teeth, for the purpose of crushing alimentary substances, is most complete in the genus *Myliobates*. A view of this armature of the mouth, as seen from behind in the *Myliobates aquila*, is given in fig. 26. Both

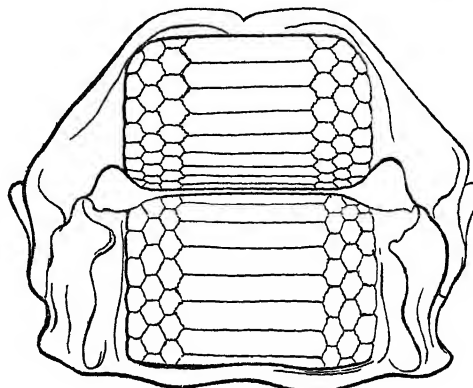

Fig. 26.
Jaws and Teeth of an Eagle-Ray (*Myliobates aquila*)

jaws are covered with a pavement of broad teeth, having a flat grinding surface, vertical and finely-undulated sides, by which

Teeth of
Fishes.

contiguous teeth are joined together, as by a suture (fig. 27, c), and a base divided into a number of small parallel longitudinal ridges.

The entire phalanx of dental plates of the upper jaw describes the segment of a circle. A longitudinal and vertical section of a single dental plate, viewed by a compound lens of an inch focus, exhibits at its base a coarse network of large irregular canals, filled with a vascular medullary pulp. From this network smaller medullary canals proceed towards the flat grinding surface, in a straight and slightly diverging course, subdividing dichotomously, with interspaces equal to their own diameter at the base, but much wider at the working surface of the tooth; under the same power, the area of the medullary canals presents generally an irregular elliptical form (fig. 27, a), from which radiating dentinal tubes are faintly perceptible. Each canal and its series of tubes is surrounded by a line of generally a hexagonal form (fig. 27, b), which constitutes the boundary between contiguous canals and tubes; the whole tooth being thus composed of an aggregate of slender, elongated, commonly six-sided prismatic teeth, placed vertically to the grinding surface. The wavy line of the suture, uniting two contiguous teeth, is shown at c.

The teeth of the *Myliobates*, like those of the rest of the Plagiostomes, are successively formed at the posterior part of the tessellated series in proportion as they are worn away in front. A series of minute and closely-aggregated papilliform matrices rise from the mucous membrane behind the teeth, and are covered by a fold of the same membrane, which is reflected forward so as to conceal the pulps of the last-formed teeth. The papilliform pulps are ossified by the deposition of the calcareous salts in the peripheral cells and radiating tubes; but the medullary or central canal of each pulp continues to retain its organized and vascular contents until the whole of the compound tooth is completed; the calcified wall of the medullary canal is then thickened, and the area diminished, by the successive formation of concentric laminae of osseous matter.

As the teeth of the *Myliobates* are gradually carried forwards into action by the direction of growth of their basis of support, the area of the medullary canals become progressively diminished, as in bone, by osseous deposition in concentric layers, and they thus become finally consolidated in the anterior teeth.

Cestracionts.

The dental characters of this family of cartilaginous fishes are chiefly manifested in a form of tooth better adapted for crushing or comminuting alimentary substances which offer only passive resistance, than for piercing, cutting, and lacerating a living prey; and in most of the species the teeth vary in form and size in the same individual to a greater degree than in the sharks. Of the numerous singular forms of this tribe of cartilaginous fishes that once peopled the seas of the Northern Hemisphere, and which have left their less perishable remains in the secondary strata of the present dry land, all have now disappeared, and the sole existing representative is the genus *Cestracion*, of which the most common species is met with in the Australian seas. The ancient fossils above alluded to would have been scarcely intelligible, unless the key to their nature had been afforded by the teeth and spines of the existing *Cestracion*. In the Port Jackson shark (*Cestracion Phillippii*), the jaws form a greater proportion of the skull than in any other existing cartilaginous and plagiostomous fish. They are also more elongated, and directed more horizontally forward, thus approaching nearer to the usual position of the jaws in the osseous fishes. The teeth are arranged, as in the Plagiostomes generally, in several antero-posterior rows along the margin and inner surface of both jaws (fig. 28); but the rows are more oblique than in the sharks, although less so than in certain rays,—e.g., *Rhina*. The teeth of the upper jaw are delineated in fig. 28. Those at the anterior part of the jaws are the smallest; they present a transverse, subcompressed, conical figure, with the apex produced into a sharp point; the points are worn away from the used teeth at the anterior and outer parts of the jaw, but are strongly marked in those which still lie below the margin. There are six subvertical rows of these small cuspidate teeth on each side of the jaw, together with a median row close to

the symphysial line, and there are from twelve to fourteen teeth in a row. Behind the cuspidate teeth the five consecutive rows of teeth progressively increase in all their dimensions, but principally in their antero-posterior extent. The sharp point is converted into a longitudinal ridge traversing a convex crushing surface, and the

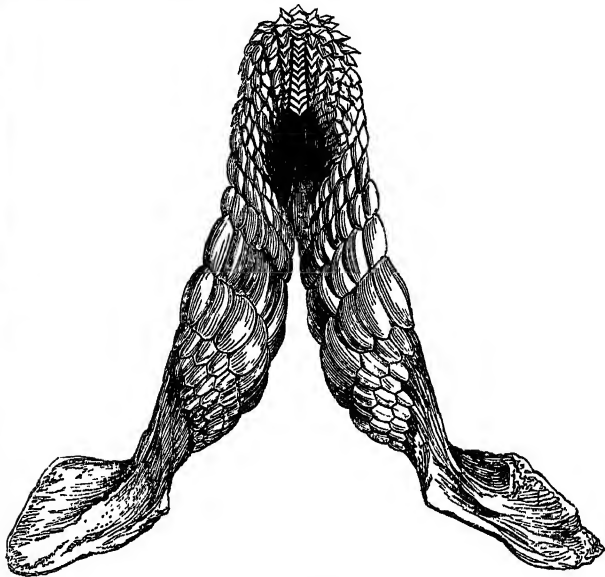

Fig. 28.
Upper Jaw and Teeth of Port Jackson Shark (*Cestracion*), half nat. size.

ridge itself disappears in the largest teeth. As the teeth increase in size, they diminish in number in each row. The series of the largest teeth includes from six to seven in the upper, and from seven to eight in the lower jaw. Behind this row the teeth, although preserving their form as crushing instruments, progressively diminish in size, while at the same time the number composing each row decreases. From the oblique and apparently spiral disposition of the rows of teeth, their symmetrical arrangement on the opposite sides of the jaw, and their graduated diversity of form, they constitute the most elegant tessellated covering to the jaws which is to be met with in the whole class of fishes.

The modifications of the form of the teeth above described, by which the anterior ones are adapted for seizing and retaining, and the posterior for cracking and crushing alimentary substances, are frequently repeated, with various modifications and under different conditions, in the osseous fishes. They indicate, in the present cartilaginous species, a diet of a lower organized character than in the true sharks; and a corresponding difference of habit and disposition is associated therewith. The testaceous and crustaceous invertebrate animals constitute most probably the principal food of the *Cestracion*, as they appear, by their abundant remains in secondary rocks, to have done in regard to the extinct *Cestracionts*, with whose fossil teeth they are associated.

From the extensive series of osseous fishes, the limits of the present article compel a selection of a few of the more remarkable modifications of the dental system.

Genus ANARHICAS.—The cat-fish or wolf-fish (*Anarhicas lupus*) *Anarhicas* has two kinds of teeth with well-marked distinction of form, according to which they might be termed laniaries or canines, and molars. The anterior teeth (fig. 29, a) form strong cones, and diverge so as to act as grappling hooks, well fitted for a firm grasp of the mailed body of a struggling lobster, or for extracting the shell-fish from his rocky recess or sandy burrow. The back teeth c are like paving-stones, and are powerful crushers. The premaxillary teeth (fig. 29, a) are all conical, and arranged in two rows; there are two, three, or four in the exterior row, at the mesial half of the bone, which are the largest; and from six to eight smaller teeth are irregularly arranged behind. There are three large, strong, diverging laniaries at the anterior end of each premandibular bone (fig. 29), and immediately behind these an irregular number of shorter and smaller conical teeth, which gradually exchange this form for that of large obtuse tubercles; these extend backwards, in a double alternate series, along a great part of the alveolar border of the bone, and are terminated by two or three smaller teeth in a single row, the last of which again presents the conical form. Each palatine bone supports a double row of teeth, the outer ones being conical and straight, and from four to six in number; the inner ones two, three, or four in number, and tuberculate. The lower surface of the vomer (fig. 29, c) is covered by a double

Teeth of Fishes. irregularly alternate series of the same kind of large tuberculate crushing teeth as those at the middle of the premandibular bone.

Fig. 29.
Upper and Lower Jaws and Teeth of the Wolf-fish (*Anarhicas lupus*),
half nat. size.

All the teeth are anchylosed to more or less developed alveolar eminences, but a narrow line of demarcation is long discernible (as at 2, fig. 30). From the enormous development of the muscles

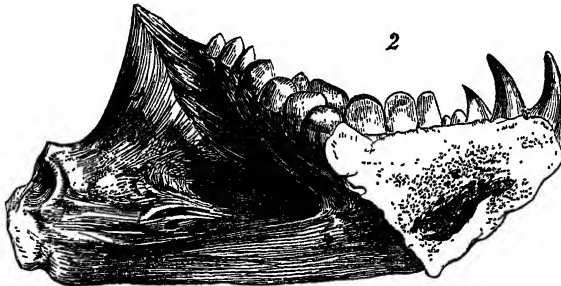

Fig. 30.
Section of Lower Jaw and Teeth of *Anarhicas lupus*, half nat. size.

of the jaws, and the strength of the shells which are cracked and crushed by the teeth, their fracture and displacement must obviously be no unfrequent occurrence: and most specimens of the jaws of the wolf-fish exhibit some of the teeth either separated at this line of imperfect anchylosis, or more rarely, broken off above the base, or, still more rarely, detached by fracture of the supporting osseous alveolar process.

Lophius.

The angler (*Lophius piscatorius*) has teeth on the premaxillary, premandibular, palatine, vomerine, and pharyngeal bones. They are of an elongated, conical, sharp-pointed, and slightly incurved form, presenting merely difference of size, degree of curvature, and mode of fixation, but all bespeaking the predatory and carnivorous habits of the species. In the upper jaw, the teeth are congregated in three or four irregular rows at the median or upper third part of each premaxillary bone, and form a single and regular series along the lower two-thirds of the same bone. These latter, which may be termed the *serial teeth*, are from fifteen to eighteen in number; they are short, strong, pointed, and incurved, of nearly equal size, and placed at regular distances from each other. The two outer irregular rows of the median intermaxillary teeth are somewhat larger, and are directed forwards. The inner rows at this part contain the longest teeth, and their points are turned back; but they are movably connected with the bone by a mechanism which will be described when treating of those of the lower jaw. The superior pharyngeal teeth are arranged in three groups upon as many separate bones on each side; each group describes a curve, with the convexity turned forwards. The teeth of the posterior bone are the smallest. The inferior pharyngeal

bones are two in number, and have the teeth arranged in a double alternate row along each margin.

The pharyngeal, palatine, and vomerine teeth are fixed by anchylosis to their respective bones; this is also the case with most of the premaxillary teeth, and with the exterior teeth of the lower jaw (fig. 31, *a, a*), but the remainder, and especially the large posterior teeth of the lower jaw (fig. 31, *b, b*), are attached by means of elastic ligaments to the margins of slightly elevated alveolar processes. These ligaments (fig. 31, *c, c*) are principally inserted into the inner straight margin of the base of the tooth, from which their glistening fasciculi radiate to be implanted into the jaw. The rest of the base of the tooth is connected at its circumference with more lax and yielding fibrous bands, and with the mucous membrane of the mouth, which covers the alveolar tract in the interspaces of the teeth. To any attempt to bend these teeth outwards resistance is offered by the internal ligaments above described, and by the pressure of the anterior angle at the base of the tooth against the alveolar processes or raised tubercle on which it rests; but the tooth readily yields to a force acting in the opposite direction, and the

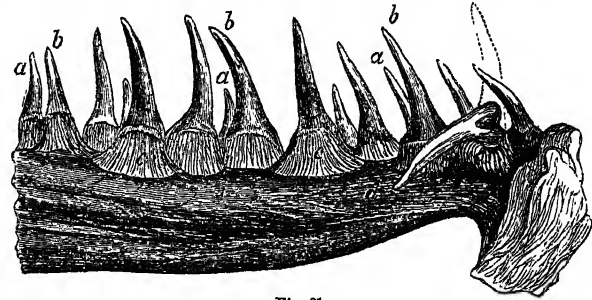

Fig. 31.
Section of Mandible and Teeth of the Angler (*Lophius piscatorius*).

largest and most prominent teeth can be bent inwards and backwards (as at *c*, fig. 31), so as to point to the gullet when the hand is pressed over them in the direction a body would take when drawn into the mouth to be swallowed. The moment, however, this force ceases to act, the teeth recoil to their erect position, as shown by the dotted outline in fig. 31) as if operated on by a spring. If everything attached to the base of the tooth, excepting the internal pyramidal band of ligamentous fibres, be removed, the tooth, after being bent down, returns with the same force to the erect position; it is therefore to this band that its resilience is due.

The cyprinoid fishes, properly so called, which are typified by Cyprinidæ, the carp and loach, respectively representing the genera *Cyprinus* and *Cobitis*, have the jaws completely deprived of teeth. The inferior pharyngeals, or throat-bones, are armed with one or more rows of teeth, which are flattened, conical, or curved, according to the species. These are succeeded by teeth at the external, as the old are shed from the internal, surface of those bones. They work against each other, and upon the very hard callous or calcified plate which is fixed in a depression on the inferior surface of the basi-occipital bone. The omnivorous barbels (*Barbus* and *Labeobarbus*) have three rows of pharyngeal teeth, which are weaker in the latter genus. In *Acanthopsis* the pharyngeal teeth are sharp-pointed, and are placed in a single row. In the loaches (*Cobitis*), which feed on worms and aquatic insects, the pharyngeals are attenuated, with chisel-shaped extremities. In the gudgeons (*Gobio*), which feed on worms, aquatic larvæ, and small molluscos animals, with their ova or fry, the pharyngeal teeth are conical, slightly curved at the extremity, and arranged in two rows. In the carp (*Cyprinus Carpio*), which feeds on the soft part of aquatic plants, larvæ of insects and worms, the pharyngeal teeth have broad, flat-ridged crowns, like the molars of herbivorous quadrupeds.

In the globe-fishes (*Diodon*), the lamellated structure of the tooth, Diodon, and its reproduction by successive transudation of layers from a persistent pulp, were supposed to be clearly demonstrated in the broad rounded triturating tubercle which is situated behind the alveolar border of the upper and lower jaw. The exposed surface of this tooth presents, in fact, a series of transverse and parallel striae, which in a vertical section (fig. 32) are seen to be the margins of thin, superimposed, horizontal, and slightly flexuous plates *a, b*, which have been partially abraded by trituration in an oblique plane. The superior layers are the most worn; in proportion as they descend, in the lower jaw, they increase in breadth, and finally, instead of being soldered together, they become detached, thinner, and of a more friable texture; the lowest and incompletely developed plates lying loosely in the cavity of the jaw, beneath the superincumbent mass (as at *a*, fig. 32). If a vertical section of the dental tubercle be made on one side of the median plane, the

Teeth of Fishes.

Cyprinidæ.

Teeth of Fishes.

laminæ are seen to be developed in two distinct lateral moieties, which become ankylosed together by means of a thin median vertical osseous partition at their median margins; their lateral margins are similarly ankylosed to the outer walls of the dentigerous cavity. The laminæ are developed successively; and in proportion as the anterior ones are worn away, the posterior ones appear in readiness to replace them; so that the due number of ridges on the triturating surface is always maintained.

To examine the structure of the lamelliform denticles, it is necessary to make extremely thin sections in a direction vertical to their plane. Each plane then exhibits, instead of an amorphous or sub-crystalline mass of excreted calcareous matter, a series of extremely minute dentinal tubes, occupying its whole extent, and having a general direction vertical to its plane. The tubes are obviously wider at the lower side of the plate, and gradually disappear in the clear and dense substance at the opposite surface. When the thinnest and most transparent parts of the same section are examined with a compound lens of $\frac{1}{2}$ -inch focus, the horizontal partitions which occupy the interspaces of the lamelliform teeth are seen to consist of a coarse cellular osseous texture, without any radiating cells, but similar to the texture of the rest of the endo-skeleton of the *Diodon*. The main tubes of the dental plate are continued immediately from the cells of the osseous septum; they proceed for a short distance vertically, or with a slight curvature, in the substance of the dental plate, and then quickly divide and subdivide, the branches generally coming off at an angle of 45° , being slightly bent, crossing each other in an inextricable manner, and terminating ultimately in the clear matrix of the upper surface of the dental plate. By the time that calcification has begun in one pulp, a second has been developed beneath it, and it is the portion of the pulp solidified which gives rise, in the macerated and dried jaws, to the loose and thin lamellæ in the dental cavity. These lamellæ become fixed by means of the coarser calcification or ossification which subsequently takes place in the remains of the pulp; and their margins are thus ankylosed to the surrounding bones in a manner analogous to the fixation of the base of the ordinary shaped teeth in other fishes.¹

Scarus.

Genus SCARUS.—The dense tessellated covering of the beak-like jaws (fig. 33) of the parrot-fishes (*Scarus*) consists of a stratum of

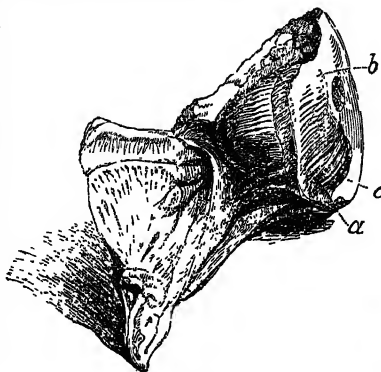

Fig. 32.
Section of Jaw and Dental Mass of a Globe-fish (*Diodon*).

The irritable bodies of the gelatinous polypes, which constitute the food of these fishes, retract, when touched, into their star-shaped stony shells; and the *Scari* consequently require a dental apparatus strong enough to break off or scoop out these calcareous recesses. The jaws are therefore prominent, short, and stout; and the exposed portions of the premaxillaries and premandibulars are encased by the complicated dental covering represented in figs. 33 and 34. The polypes and their cells are reduced to a pulp by the

Teeth of Fishes.

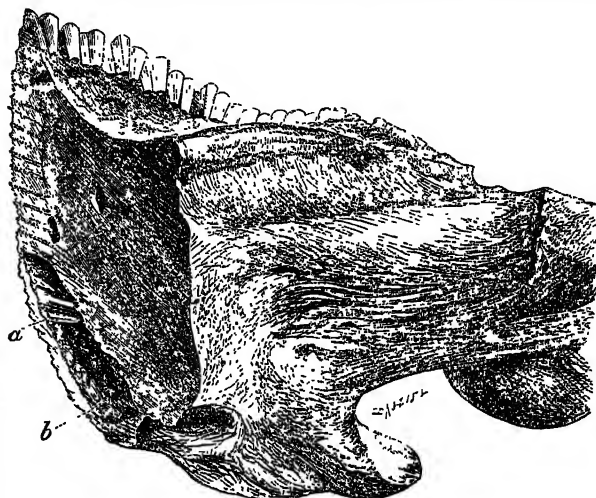

Fig. 34.
Section of Premandibular Bone and Teeth of Parrot-fish (*Scarus muricatus*).

action of the pharyngeal jaws and teeth (fig. 35) that close the posterior aperture of the mouth.

The typical *Scari* have both upper and lower pharyngeal bones paved with strong, thick lamelliform teeth, set vertically and transversely in the opposed surfaces of these bones. It is the posterior pair of the upper pharyngeals (fig. 35) which are thus armed. The lower pharyngeal bone is single.

The superior dentigerous pharyngeals present each the form of an elongated vertical inequilateral triangular plate; the upper and posterior margin is sharp and concave; the upper and anterior margin forms a thickened articular surface, convex from side to side, and playing in a corresponding groove or concavity upon the base of the skull; the inferior boundary of the triangle is the longest, and also the broadest; it is convex in the antero-posterior direction, and flat from side to side. It is on this surface that the teeth are implanted; and in most species they form two rows, the outer one consisting of very small teeth (fig. 35, a), the inner one of large teeth b. These present the form of compressed conical plates or wedges, with the basis excavated and the opposite margin moderately sharp, and slightly convex to near the inner angle, which is produced into a point. These plates are set nearly transversely across the lower surface of the pharyngeal bone, and are produced beyond the margin of the bone, and interlock with those of the adjoining bone when the pharyngeals are in their natural position. The smaller denticles of the outer row are set in the external interspaces of those of the inner row.

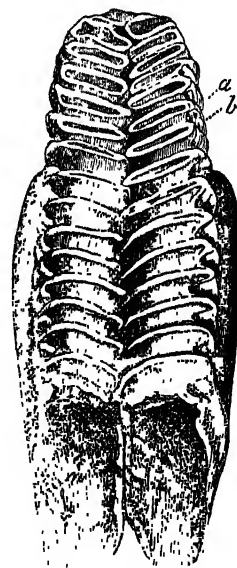

Fig. 35.
Upper Pharyngeal Bones and Teeth of a Parrot-fish (*Scarus muricatus*).

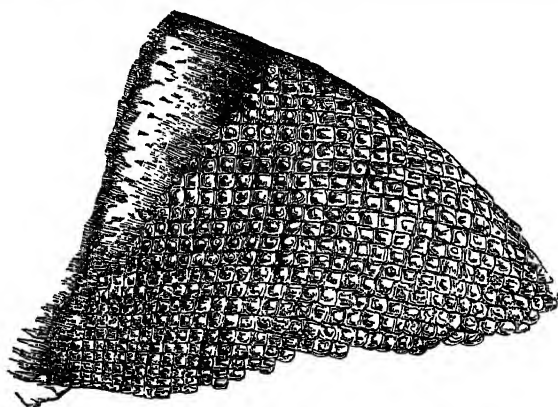

Fig. 33.
Premaxillary Bone and Teeth of a Parrot-fish (*Scarus muricatus*).

prismatic denticles (fig. 34, a), standing almost vertically to the external surface of the jaw-bone, the square tuberculate ends of which appear externally wedged close together, like the blocks in wood-pavement. This peculiar armature of the jaws is well adapted to the habits and exigencies of a tribe of fishes which browse upon the lithophytes that clothe, as with a richly-tinted carpet, the bottom of the sea, just as the ruminant quadrupeds crop the herbage of the dry land.

The dentine of the pharyngeal teeth of the *Scarus* consists of dentinal tubes and a clear intermediate substance. The tubes average a diameter of $\frac{1}{100}$ of an inch, and are separated by interspaces equal to twice their own diameter; and these tubes, on leaving the pulp-cavity, form a curve with the convexity turned towards the base of the tooth, and then bend slightly in the opposite direction; the sigmoid curve being most marked in the tubes at the base of the denticles, whilst those towards the apex become longer and

¹ For other details of the gymnodont dentition, see *Annales des Sciences Naturelles*, 2de série, tom. xii., p. 347.

Teeth of
Fishes

straighter. Besides the primary curvatures exemplified in the figure, each dentinal tube is minutely undulated; it dichotomizes three or four times near its termination, sends off many fine lateral branches into the clear uniting substance, and finally terminates in a series of minute cells and inosculating loops, at the line of junction with the enamel.

This substance is as thick as the dentine, and consists of a similar combination of minute tubes and a clear connecting substance. The tubes may be described as commencing from the peripheral surface of the tooth, to which they stand at right angles; and having proceeded parallel to each other half-way towards the dentine, they then begin to divide and subdivide, the branches crossing each other obliquely, and finally terminating in the cellular boundary between the enamel and dentine.

The teeth which present this complex structure are successively developed at one extremity of the bone in proportion as they are worn away at the other—not, however, as Cuvier describes, from behind forwards in both upper and lower pharyngeal bones, but in opposite directions in the opposite bones, the course of succession being from before backwards in the upper, and from behind forwards in the lower pharyngeal bones. In the progress of the attrition to which they are subjected, the thin coat of cement resulting from the ossification of the capsule is first removed from the apex of the tooth, then the enamel constituting that apex, next the dentine, and finally the coarse central cellular bone supporting the hollow wedge-shaped tooth; and thus is produced a triturating surface of four different substances of different degrees of density. The enamel, being the densest element, appears in the form of elliptical transverse ridges inclosing the dentine and central bone; and external to the enamel is the cement which binds together the different denticles.

The single inferior pharyngeal bone consists principally of an oblong dentigerous plate. Its breadth somewhat exceeds that of the conjoined dentigerous surfaces of the pharyngeals above; and it is gently hollowed, to correspond with their convexity. This dentigerous plate is principally supported by a strong, slightly curved, transverse, osseous bar, the extremities of which expand into thick obtuse processes for the implantation of the triturating muscles. A longitudinal crest is continued downwards and forwards from the middle line of the inferior pharyngeal plate, anterior to the transverse bar, to which the protractor muscles are attached.

A longitudinal row of small oval teeth, alternating with the large lamelliform teeth, like those of the superior pharyngeals, bounds the dentigerous plate on each side. The intermediate space is occupied exclusively by the larger lamelliform or wedge-shaped teeth, set vertically in the bone, and arranged transversely in alternate and pretty close-set rows.

There is a close analogy between the dental mass of the *Scarus* and the complicated grinders of the elephant, both in form, structure, and in the reproduction of the component denticles in horizontal succession. But in the fish the complexity of the triturating surface is greater than in the mammal, since, from the mode in which the wedge-shaped denticles of the *Scarus* are implanted upon, and ankylosed to, the processes of the supporting bone, this likewise enters into the formation of the masticatory surface when the tooth is worn down to a certain point.

The proof of the efficacy of the complex masticatory apparatus above described is afforded by the contents of the alimentary canal of the *Scari*. Mr Charles Darwin, the accomplished naturalist and geologist, who accompanied Captain Fitzroy, R.N., in the circumnavigatory voyage of the *Beagle*, dissected several parrot-fishes soon after they were caught, and found the intestines laden with nearly pure chalk, such being the nature of their excrements; whence he ranks these fishes among the geological agents to which is assigned the office of converting the skeletons of the lithophytes into chalk.

Sphyræna. Genus SPHYRÆNA.—The most formidable dentition in the order of osseous fishes is that which characterizes the Barracuda sea-pikes (*Sphyræna*), and some extinct fishes allied to this predatory genus. In the great Barracuda of the southern shores of the United States (*Sphyræna barracuda*, Cuv.), the lower jaw contains a single row of large, compressed, conical, sharp-pointed, and sharp-edged teeth, resembling the blades of lancets, but stronger at the base. The two anterior of these teeth are twice as long as the rest; but the posterior and serial teeth gradually increase in size towards the back part of the jaw. There are about twenty-four of these piercing and cutting teeth in each premandibular bone. They are opposed to a double row of similar teeth in the upper jaw, and fit into the interspace of these two rows when the mouth is closed. The outermost row is situated on the premaxillary, the innermost on the palatine bones. There are no teeth on the vomer or superior maxillary bones. The two anterior teeth in each premaxillary bone equal the opposite pair in the lower jaw in size; the posterior pre-

maxillary teeth are serial, numerous, and of small size; the second of the two anterior large premaxillary teeth is placed on the inner side of the commencement of the row of small teeth, and is a little inclined backwards. The retaining power of all the large anterior teeth is increased by a slight posterior projection, similar to the barb of a fish-hook, but smaller. The palatine bones contain each nine or ten lancet-shaped teeth, somewhat larger than the posterior ones of the lower jaw. All these teeth afford good examples of the mode of attachment by implantation in sockets, which is a rare one in the class of fishes.

The base or fang of the fully-developed tooth of the *Sphyræna* is ankylosed to the parietes of the socket in which it is inserted. The pressure of the crown of the new tooth excites absorption of the inner side of the base of the old, which thus finally loses the requisite strength of attachment, and its loss is followed by the absorption of the old socket, as in the higher animals.

It is interesting to observe that the external teeth are in general contemporaneously shed, so that the maxillary armour is always preserved in an effective state. The relative position of the new teeth to their predecessors, and their influence upon them, resembles some of the phenomena which will be described in the dentition of the crocodilian reptiles. To the crocodiles the present voracious fish also approximates in the alveolar lodgment of the teeth; but it manifests its ichthyic character in the ankylosis of the fully-developed teeth to their sockets, and still more strikingly in the intimate structure of the teeth. The loss or injury to which these destructive weapons are liable in the conflict which the *Sphyræna* wages with its living and struggling prey is repaired by an uninterrupted succession of new pulps and teeth. The existence of these is indicated by the foramina, which are situated immediately posterior to, or on the inner margins of, the sockets of the teeth in place. These foramina lead to alveoli of reserve, in which the crowns of the new teeth, in different stages of development, are loosely imbedded. It is in this position of the germs of the teeth that the sphyrenoid fishes, both recent and fossil, mainly differ as to their dental characters from the rest of the scomberoid family, and proportionally approach the sauroid type.

In all fishes the teeth are shed and renewed, not once only, as in mammals, but frequently during the whole course of their lives. The maxillary dental plates of *Lepidosiren*, the cylindrical dental masses of the chimæroid and edaphodont fishes, and the rostral teeth of the *Pristis* (if these modified dermal spines may be so called), are perhaps the sole examples of permanent teeth to be met with in the whole class. In the great majority of fishes the germs of the new teeth are developed, like those of the old, from the free surface of the buccal membrane throughout the entire period of succession; a circumstance peculiar to the present class. The angler, the pike, and most of our common fishes, illustrate this mode of dental reproduction; it is very conspicuous in the cartilaginous fishes, in which the whole phalanx of their numerous teeth is ever marching slowly forwards in rotatory progress over the alveolar border of the jaw; the teeth being successively cast off as they reach the outer margin, whilst the new teeth rise from the mucous membrane behind the rear rank of the phalanx. This endless succession and decadence of the teeth, together with the vast numbers in which they often co-exist in the same fish, illustrate the law of "vegetative" or "irrelative repetition," as it manifests itself on the first introduction of new organs in the animal kingdom; under which light we must view the above-described organized and calcified preparatory instruments of digestion in the lowest class of the vertebrate series.

At the extreme limit of the class of fishes, and connecting that *Lepidosiren* class with the reptiles, stands the very remarkable genus, the dental ren. system of which is shown in fig. 36. This consists of two small,

Fig. 36.

Skull and Teeth of the *Lepidosiren annecteus*.

slender, conical, sharp-pointed, and slightly recurved teeth, which project downward from the nasal bone *a*, and of strong trenchant dental plates, ankylosed with the alveolar border of the upper (*b*) and lower (*c*) jaw, in each of which the plate is divided at the middle or symphyseal line, so as to form two distinct lateral teeth.

The office of the two lanianiform teeth is to pierce and retain the

Teeth of
Fishes.

Teeth of Reptiles.

nutritive substance or prey, which is afterwards divided and comminuted by the strong maxillary dental plates. The upper pair of these plates is supported by the anterior part of a strong arch of bone, which combines the character of the superior maxillary, palatine, and pterygoid bones. The superior maxillary is represented by the median and anterior bar, passing in front of the dental plate of the lower jaw when the mouth is shut, and terminating on each side in a process which projects outwards and backwards on each side of the anterior part of the arch; the palatine portion constitutes the median part of the roof of the mouth behind the foregoing. The pterygoid portion is indicated by its fulfilling the usual function of an abutment extended between the palatine portion of the upper jaw and the articular pedicle of the lower jaw. The upper dental plates are confined to the first two parts of the arch (maxillary and palatine), and do not extend upon the pterygoid portion; the lower dental plates are ankylosed to the premandibular bone. Viewing the upper pair of plates as a single tooth, it may be described as indented at its outer surface by five vertical angular notches, penetrating inwards through half the breadth of the supporting bone, and dividing the plate into six angular processes, which, from the direction and varying form and breadth of the entering notches, radiate from the posterior part of the median line or division of the tooth. The inferior dental plate is similarly notched on its outer side, but the proportions of the angular indentations are such that they receive all the processes of the upper dental plate when the mouth is shut, whilst only the four anterior processes are reciprocally received into the notches of the upper dental plate. The dental plate consists, as in the cod and *Sphyrana*, of a central mass of coarse osseous substance traversed by large and nearly parallel medullary canals, and an external sheath of very hard "vitrodentine."

Dendrodonts.

The labyrinthine structure of the teeth of the bony gar-fish of the North American lakes and rivers (*Lepidosteus*) has been already alluded to in the introductory generalization on dental tissues. The still more complex structure of the fossil teeth of the extinct Dendrodonts (fig. 14) is there more fully described. As compared with the vasodentine (fig. 7) of the sharks and of many existing osseous fishes, the dental tissue of the Dendrodonts differs in both the extent and regularity of the radiating medullary canals, and more especially in the straight course of the fine dentinal tubes.

Both the foregoing genera of fishes have been termed "sauroid," but are more truly "salamandroid," and approach, like the Lepidosiren, most closely to the lower confines of the reptilian class; and as this existing annectant genus is allied to the perennibranchiate Batrachians, so the *Dendrodus* may have linked some extinct group of the class of fishes with the equally extinct family of sauroid Batrachians which have been termed "Labyrinthodonts."

SECT. II.—TEETH OF REPTILES.

In the class Reptilia, the whole order of *Chelonia* is edentulous, as well as the family of toads (*Bufonidae*), in the order *Batrachia*; certain extinct genera of Saurians were edentulous, e.g., the remarkable *Rhynchosaurus* of the New Red Sandstone of Shropshire, and some of the extinct Saurians of South Africa.

In the tortoises and turtles, the jaws are covered by a sheath of horn, which in some species is of considerable thickness, and very dense; its working surface is trenchant in the carnivorous species, but variously sculptured, and adapted for both cutting and bruising, in the vegetable feeders; it may be said that the transitory condition of the mandibles of the batrachian larvæ is here persistent. The development of the continuous horny maxillary sheath commences, as in the parrot tribe, from a series of distinct papillæ, which sink into alveolar cavities, regularly arranged (in *Trionyx*) along the margins of the upper and lower jaw-bones; these alveoli are indicated by the persistence of vascular canals long after the originally separate tooth-like cones have become confluent and the horny sheath completed. The teeth of the dentigerous saurian, ophidian, and batrachian reptiles are for the most part simple, and adapted for seizing and holding, but not for dividing or masticating their food. The siren alone combines true

teeth with a horny maxillary trenchant sheath, like that of the chelonian reptiles.

Teeth of Reptiles.

With respect to *number*, in no existing reptiles are the teeth reduced so low as in certain mammals and fishes; nor, on the other hand, are they ever so multiplied as in many of the latter class. The extinct dicynodont reptiles of South Africa had but two teeth, which were long tusks implanted in the upper jaw (fig. 44).¹ Some species of *Amphisbæna* (*A. alba*), with fifteen teeth in the upper jaw and fourteen in the lower, afford examples of the smallest number of teeth amongst existing reptiles; and certain Batrachians, with teeth "en cardes" at the roof of the mouth, or which have upwards of eighty teeth in each lateral maxillary series, present the largest number. It is rarely that the number of the teeth is fixed and determinate in any reptile, so as to be characteristic of the species; and still more rarely have the individual teeth such characters as to be determined homologically from one species to another.

The teeth of reptiles, with few exceptions, present a *Form*. simple conical *form*, with the crown more or less curved, and the apex more or less acute. The cone varies in length and thickness; its transverse section is sometimes circular, but more commonly elliptical or oval, and this modification of the cone may be traced through every gradation, from the thick, round, canine-like tooth of the crocodile, to the sabre-shaped fang of the Varanus, the Megalosaur, and Cladeiodon.² Sometimes, as in the fully-formed teeth of the Megalosaur, one of the margins of the compressed crown of the tooth is trenchant, sometimes both are so; and these may be simply sharp-edged, as in the Varanus of Fimor, or finely serrated, as in the great Varanus, the Cladeiodon, and the Megalosaur.³

The outer surface of the crown of the tooth is usually smooth: it may be polished, as in the Leiodon; or impressed with fine lines, as in the Labyrinthodon (fig. 11); or raised into many narrow ridges, as in the Pleiosaur and Polyptychodon; or broken by a few broad ridges, as in the Iguanodon (fig. 42); or grooved by a single longitudinal furrow, as in some lizards and serpents (fig. 38).⁴

The cone is longest, and its summit sharpest, in the serpent; from these may be traced, chiefly in the lizard tribe, a progressive shortening, expansion of the base, and blunting of the apex of the tooth, until the cone is reduced to a hemispherical tubercle or plate, as in the Thorictes and Cyclodus. The extinct *Placodus* was remarkable for the great size of its flat crushing teeth; in one species (*Pl. laticeps*) the diameter of the crown of the last palatal tooth is one inch four lines, the length of the skull being eight inches: this is the largest proportional grinding-tooth in the animal kingdom. In the Pleiosaur, the dental cone is three-sided, with one of the angles rounded off. The posterior subcompressed teeth of the alligator (fig. 46) present a new modification of form; here they terminate in a mammillate summit, supported by a slightly constricted neck. In the tooth of the Hylæosaur the expanded summit is flattened, bent, and spear-shaped, with the edges blunted. But the breadth of the compressed crown is greatest in the subcompressed teeth of the extinct Cardiodon and the existing Iguanas, the teeth of which latter reptiles are further complicated by having the margins notched. The great Iguanodon had the crown of the tooth expanded both in length and breadth, and combined marginal dentations with longitudinal ridges; this tooth (fig. 42) presents the most complicated external form as yet discovered in the class of reptiles. In no reptiles does the base of the tooth ever branch into fangs.

With respect to *situation*, the teeth may be present on

¹ *Transactions of the Geological Society*, 2d series, vol. vii., p. 59.

⁴ *Ibid.*, pl. lxx.

Teeth of
Reptiles.

the jaws only,—viz., the maxillary, premaxillary, and mandibular bones, as in the crocodiles, and many lizards; or upon the jaws and roof of the mouth; and here, either upon the pterygoid bones, as in the Iguana and Mosasaur; or upon both palatine and pterygoid bones, as in most serpents; or upon the vomer, as in most Batrachians; or upon both vomerine and pterygoid bones, as in the Axolotl; or upon the vomerine and phenoid bones, as in the *Salamandra glutinosa*, Maclure. With respect to the marginal or jaw teeth, these may be absent in the premaxillary bones, as in many serpents; or they may be present in the upper and not in the lower jaw, as in most frogs; or in both upper and lower jaws, as in the tailed Batrachians; and among these they may be supported, upon the lower jaw, by the premandibular or dentary piece, as in the Salamander, Menopome, Amphiume, Proteus; or upon the splenial piece,¹ as in the Siren; or upon both the splenial and premandibular bones, as in the Axolotl. The palatine and pterygoid teeth may, in the Batrachians, be arranged in several rows, like the “dents en cardes” of fishes. The sphenoid and splenial teeth are always so arranged in the few species that possess them. The premaxillary, maxillary, and premandibular teeth are uniserial, or in one row, with the exception of the *Cæcilia*, and the extinct Labyrinthodonts, which have a double row of teeth at the anterior part of the lower jaw.

Attach-
ment.

As a general rule, the teeth of reptiles are ankylosed to the bone which supports them; when they continue distinct, they may be lodged either in a continuous groove, as in the Ichthyosaurs,² or in separate sockets, as in the Plesiosaurs and crocodiles (fig. 46).

The base of the tooth is ankylosed to the walls of a moderately deep socket in the extinct Megalosaur and Thecodon. In the Labyrinthodonts and Cæciliæ, among the Batrachians, in most Ophidians,—and in the Geckos, Agamians, and Varanians, among the Saurians,—the base of the tooth is imbedded in a shallow socket, and is confluent therewith. In the Scincoidians, the safeguards (*Tejus*) in most Iguanians, in the Chameleons, and most other lacerian reptiles, the tooth is ankylosed by an oblique surface, extending from the base, more or less, upon the outer side of the crown, to an external alveolar plate of bone,³ the inner alveolar plate not being developed. In the frogs, the teeth are similarly but less firmly attached to an external parapet of bone. The lizards, which have their teeth thus attached to the side of the jaw, are termed “Pleurodont.” In a few Iguanians, as the Istiures, the teeth appear to be soldered to the margins of the jaws; these have been termed “Acrodonts.” In some large extinct Lacertians,—e.g., the Mosasaur and Leiodon,—the tooth is fixed upon a raised conical process of bone, as shown in the author’s “Odontography,” plate 68, fig. 1; and plate 72, fig. 2.

These modifications of the attachment of the teeth of reptiles are closely adapted to the destined application of those instruments, and relate to the habits and food of the species: we may likewise perceive that they offer a close analogy to some of the transitory conditions of the human teeth. There is a period, for example,⁴ when the primitive dental papillæ are not defended by either an outer or an inner alveolar process, any more than their calcified homologues, which are confluent with the margin of the jaw in the Rhynchocephalus.⁵ There is another stage,⁶ in which the groove containing the dental germs is defended by a single external cartilaginous alveolar ridge; this condition is permanently typified in the *Cyclodus*, and most existing lizards (fig. 41). Next, there is developed in the

human embryo an internal alveolar plate, and the sacs and pulps of the teeth sink into a deep but continuous groove, in which traces of transverse partitions soon make their appearance: in the ancient Ichthyosaur the relation of the jaws to the teeth never advance beyond this stage. Finally, the dental groove is divided by complete partitions,⁷ and a separate socket is formed for each tooth; and this stage of development is attained in the highest organized reptiles—e.g., the crocodiles.

Teeth of
Reptiles.

The tissues entering into the composition of reptilian Substance. teeth may be four-fold, and a single tooth may be composed of dentine, cement, enamel, and bone; but the dentine and cement are present in the teeth of all reptiles. In the Batrachians and Ophidians a thin layer of cement invests the central body of dentine, and, as usual, follows any inflections or sinuosities that may characterize the dentine. Besides the outer coat of cement, which is thickest at the base of the teeth, a generally thin coat of enamel defends the crown of the tooth in most Saurians, and the last remains of the pulp are not unfrequently converted into a coarse bone, both in the teeth which are ankylosed to the jaw, and in some teeth, as those of the Ichthyosaur, which remain free. The only modification of the dentine, which could at all entitle it to be regarded in the light of a new or distinct substance, is that which is peculiar in the present class to the teeth of the Iguanodon, and which will be presently described.

The varieties of dental structure are few in the rep- Structure. tiles, as compared with either fishes or mammals, and its most complicated condition arises from interblending of the dental and other substances, rather than from modifications of the tissues themselves. In the teeth of most reptiles, the intimate structure of the dentine corresponds with that which has been described as the type of the tissue,—e.g., the hard or unvascular dentine,—and which is the prevailing modification in mammals, viz.,—the radiation of a system of minute plasmatic tubes from a single pulp-cavity, at right angles to the external surface of the tooth. The most essential modification of this structure is the intermingling of cylindrical processes of the pulp-cavity in the form of medullary canals, with the finer tubular structure.⁸ Another modification is that in which the dentine maintains its normal structure, but is folded inwardly upon itself, so as to produce a deep longitudinal indentation on one side of the tooth. It is the expansion of the bottom of such a longitudinal deep fold that forms the central canal of the venom-fang of the serpent; but a glance at fig. 39 will show that, notwithstanding the singularly modified disposition of the dentine (*b*), its structure remains unaltered; and although the pulp-cavity (*p*) is reduced to the form of a crescentic fissure, the dentinal tubes continue to radiate from it according to the usual law. By a similar inflection of many vertical longitudinal folds of the external cement and external surface of the tooth, at regular intervals around the entire circumference of the tooth, and by a corresponding extension of radiated processes of the pulp-cavity and dentine into the interspaces of such inflected and converging folds, a modification of dental structure is established in certain extinct reptiles, which, by the various sinuosities of the interblended folds of cement, and processes of dentine, with the partial dilations of the radiated pulp-cavity, produces the complicated structure, which has been described at page 412, and figured in cut 12. But this complication is, nevertheless, referable to a modification of form or arrangement of the dental tissues, rather than of their number in the same tooth: the dentinal tubes in each

Teeth of
Reptiles.Develop-
ment.

sinuous lobe of dentine in the most complex tooth of the *Labyrinthodon* exhibit the same general disposition and course as in the fang of the serpent, and in the still more simple tooth of the Saurian.

The teeth of reptiles are never completed, as in certain fishes, at the first or papillary stage; the pulp in all sinks into a follicle, and becomes inclosed by a capsule: in certain reptiles this becomes more or less surrounded by bone; but in the existing species the process of development never offers the "eruptive stage," in the sense in which this is usually understood, as signifying the extrication of the young tooth from a closed alveolus. The completion of a tooth, with the exception of the extinct dicynodont reptiles, is soon followed by preparation for its removal and succession: the faculty of developing new tooth-germs seems to be unlimited in the present class, and the phenomena of dental decadence and replacement are manifested at every period of life. The number of teeth is generally the same in each successive series, and the difference of size presented by the teeth of different and distinct series is considerable. The new germ is always developed, in the first instance, at the side of the base of the old tooth, never in the cavity of the base: the crocodiles form no exception to this rule. The poison-fangs of serpents succeed each other from behind forwards: in almost every other instance the germ of the successional tooth is developed from the bottom and towards the outer side of a small fissure in the mucous membrane or gum that fills up the shallow groove at the inside of the alveolar parapet and its adherent teeth; the papilla is soon enveloped by a capsular process of the surrounding membrane; a small enamel-pulp is developed in the matrix opposite the apex of the tooth; the deposition of the earthy salts in this mould is accompanied by ossification of the capsule, which afterwards proceeds *pari passu* with the calcification of the dentinal papilla or pulp; so that, with the exception of its base, the surface of the uncalcified part of the pulp alone remains normally unadherent to the capsule. As the tooth acquires hardness and size, it presses against the base of the contiguous attached tooth, causes a progressive absorption of that part (fig. 46, *a*), and finally undermines, displaces, and replaces its predecessor. The number of nascent matrices of the successional teeth is so great in the frog, and they are crowded so close together, that it is not unusual to find the capsules of contiguous tooth-germs becoming adherent together as their calcification proceeds. After a brief maceration, the soft gum may be stripped from the shallow alveolar depression, and the younger tooth-germs in different stages of growth are brought away with it.

The mode of development of the teeth of serpents does not differ essentially from that of the teeth of the Batrachians above described, except in the relation of the papillæ of the successional poison-fangs to the branch of the poison-duct that traverses the cavity of the loose mucous gum in which they are developed.

Batrachia.

The variations which the dental system presents in the Batrachian order of reptiles are more conspicuous in the number, situation, and structure of the teeth, than in their form or mode of attachment.

Certain Batrachians are edentulous, as the genus *Hyla-plesia*, among the tree frogs, and the *Bufo*idæ, or family of toads—some of the species of *Bombinator* excepted.

The teeth, when present, are generally numerous, simple, of small and equal size, and close-set, either in a single row, or aggregated like the teeth of a rasp.

It is not without interest to observe, that a characteristic condition of the dental system in fishes—viz., the absence of teeth on the superior maxillary bone,—is continued in those genera of perennibranchiate Batrachians which stand at the lowest steps of the reptilian class.

In the Siren (*Siren lacertina*, Linn.), the lower margin

of the intermaxillary bones, and the sloping anterior and upper margin of the lower jaw, are trenchant, and are each incased in a sheath of firm, albuminous, minutely fibrous tissue, harder than horn. The bones thus armed slide upon each other like the blades of a pair of curved scissors, when the mouth is closed, and are well adapted for dividing the bodies of small fish, aquatic larvæ, worms, &c. The splenial or opercular element in the jaw is beset with numerous minute pointed teeth, arranged in short oblique rows, and directed obliquely backwards. The palatal surface of the mouth presents on each side two flat, thin, and moderately broad bones, forming an apparently single oblique oval plate, which converges to meet its fellow at the anterior part of the palate, so as conjointly to constitute a broad rasp-like surface in the form of a chevron. The anterior long plate on each side of the divided vomer, supports six or seven oblique rows of small pointed retroverted teeth; the smallest posterior plate, probably the homologue of the pterygoid, is beset with four rows of similar teeth; there being thus ten or eleven rows on each side of the palatal chevron. The number of denticles in the middle rows is eleven or twelve; these become fewer in the anterior and posterior rows; they are all of similar size and form, corresponding with those of the lower jaw, to which they are opposed.

The condition of the dental system in this, the lowest of the Batrachia is not without interest, independently of the absence of the superior maxillary teeth, and of the presence of the palatal and inferior maxillary rasp-teeth (*dents en cardes*). The maxillary sheaths of the Siren being composed of horn, and being, moreover, easily detached from the subjacent bones, closely resemble the deciduous mandibles of the tadpoles of the higher Batrachians.

The *Proteus anguinus*, though retaining its external gills, offers a further advance to the dental characters of the higher Batrachians. The alveolar border of each intermaxillary bone is armed with a row of eight or ten minute and fine sharp-pointed teeth; each premandibular bone supports a greater number of similar but larger teeth, likewise arranged in a single row. The vomerine bones support a row of denticles, similar, and parallel to, the intermaxillary crescentic series: but the horns of the palatine dental crescent are continued much farther back, and terminate, as in the *Menobranchus*, on the anterior part of the pterygoid bones; each half of the crescentic or chevron-shaped series contains twenty-four teeth. The superior maxillary bones are represented in the *Proteus* by mere cartilaginous rudiments.

The Menopome makes a nearer approach to the caducibranchiate group, and allies itself most closely with the gigantic newt of Japan (*Sieboldtia*, Bonap.), and with that equally gigantic extinct species of newt so noted in Palæontology, as the "*Homo diluvii testis*" of Scheuchzer. The single

close-set series of small, equal, conical, and slightly recurved teeth describes a semicircle on both the upper and the lower jaws; in the former the majority are supported by true maxillary bones *b*, about eight or ten on the premaxillaries *a*. The row of similar but smaller teeth on the anterior expanded border of the divided vomer *c* runs parallel with, and at a short distance behind, the median part of the maxillary series. The premandibular teeth are received into the narrow interspace

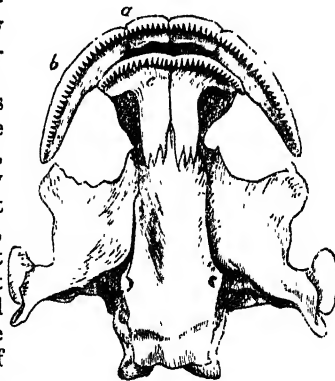

Teeth of
Reptiles.

between the two rows in the upper jaw when the mouth is closed. The teeth of the Menopome, as of the Amphiume are ankylosed by their base and part of the outer side to a slightly elevated external alveolar ridge.

Genus LABYRINTHODON.—The dental system in this extinct genus is more formidable than in any existing Batrachian, the teeth being implanted in distinct sockets, and a few of the anterior ones developed into large tusks (fig. 11).

A close-set series of subsequent teeth extends along the alveolar border of both upper and lower jaws, and along the anterior part of the outer margin of each broad vomerine bone. Both the division and dentigerous character of this bone exemplify the batrachian affinities of the reptiles in question. Two or three canine-shaped teeth, at least three times the size of the serial teeth, are placed in the premaxillary bones, also at the anterior and external angle of each vomer, at the fore-part of the maxillaries, and behind the anterior extremity of the serial teeth of the lower jaw. This allocation of teeth in a double row is peculiar, among reptiles, to the Cecilia and the present equally aberrant form of Batrachian: it is a common dental character in the class of fishes.

But the remarkable characteristic of the teeth of the Labyrinthodonts is the complex structure described in the general introduction, and illustrated in fig. 12. By this character the author, in 1841,¹ determined the nature of certain fossil teeth which had been found in a member of the New Red Sandstone series in Warwickshire, but which were of extreme rarity in that formation in England. The geological evidence at that period had left it uncertain whether this light-coloured sandstone was the equivalent of the "Keuper" or "Bunter" division of the German Trias.²

So far as the geological question depended upon the determination of the generic identity of the reptilian fossils in the English and German formations, it supported the view entertained by certain geologists as to the correspondence of the Warwick sandstones with the Keuper sandstones of Germany. And if, on the one hand, geology has in this instance derived any benefit from microscopical investigations of animal tissues, on the other hand it must be admitted, that in no instance has comparative anatomy been more directly indebted to geology than for the fossils, and the stimulus to their microscopic investigation, by means of which a knowledge has been obtained of the most beautiful and complicated modification of dental structure hitherto known, and of which no adequate conception could have been gained from investigations, however close and extensive, of the teeth of existing species of animals.

Ophidia.

The order *Ophidia*, as it is characterized in the system of Cuvier, requires to be divided into two sections, according to the nature of the food, and the consequent modification of the jaws and teeth. Certain species, which subsist on worms, insects, and other small invertebrate animals, have the tympanic pedicle of the lower jaw immediately and immovably articulated to the walls of the cranium. The lateral branches of the lower jaw are fixed together at the symphysis, and are opposed by the usual vertical movement to a similarly complete maxillary arch above; these belong to the genera *Amphisbæna* and *Anguis* of Linnæus, the latter represented by our common slow-worm. The rest of the Ophidians, including the ordinary serpents and constrictors, which form the typical members, and by far the greatest proportion of the order, prey upon living animals of frequently much greater diameter than their own; and the maxillary apparatus is conformably and peculiarly modified to permit of the requisite distension of the soft parts surrounding the mouth, and the transmission of their prey to the digestive cavity.

In the present article the description will be restricted to the dental peculiarities of the true serpents. All these subsist on animal matter, and swallow their food whole, whether they prey on living animals, as is the case in almost every species, or feed on

the eggs of birds, as in the *Deirodon scaber*, O. (*Coluber scaber*, Linn.)

Teeth of
Reptiles.

With the exception of this and some congeneric species, in which the teeth of the ordinary bones of the mouth are so minute as to have been deemed wanting, the maxillary and premandibular bones in all true Ophidians are formidably armed with sharp-pointed teeth; there is on each side of the palate a row of similar teeth supported by the palatine and pterygoid bones. In the great Pythons, and some species of boa, the premaxillary bone also supports teeth. All the teeth, whatever be their position, present a simple conical form, the cone being long, slender, and terminated by an acute apex, and the tooth is either straight, or, more commonly, bent a little beyond the base, or simply recurved, or with a slight sigmoid flexure. The teeth are thus adapted for piercing, tearing, and holding, and not for dividing or bruising. In some species certain teeth are traversed by a longitudinal groove for conveying an acrid saliva into the wounds which they inflict; in others, two or more teeth are longitudinally perforated for transmitting venom; such teeth are called "poison-fangs" (fig. 38, b), and are always confined to the superior maxillaries, and are generally placed near the anterior extremity of those bones.

In the genus *Deirodon*, the teeth of the ordinary bones of the mouth are so small as to be scarcely perceptible, and they appear to be soon lost; so that it has been described as an edentulous serpent. An acquaintance with the habits and food of this species has shown how admirably this apparent defect is adapted to its wellbeing. Its business is to restrain the undue increase of the smaller birds by devouring their eggs. Now, if the teeth had existed of the ordinary form and proportions in the maxillary and palatal regions, the egg would have been broken as soon as it was seized, and much of its nutritious contents would have escaped from the lipless mouth of the snake in the act of deglutition; but, owing to the almost edentulous state of the jaws, the egg glides along the expanded opening unbroken, and it is not until it has reached the gullet, and the closed mouth prevents any escape of the nutritious matter, that the shell is exposed to instruments adapted for its perforation. These instruments consist of the inferior spinous processes of the seven or eight posterior cervical vertebrae, the extremities of which are capped by a layer of hard cement, and penetrate the dorsal parietes of the œsophagus. They may be readily seen, even in very young subjects, in the interior of that tube in which their points are directed backwards. The shell being sawed open longitudinally by these vertebral teeth, the egg is crushed by the contractions of the gullet, and is carried to the stomach, where the shell is no doubt soon dissolved by the acid gastric juice.

In the boa-constrictor, the teeth are slender, conical, suddenly bent backwards and inwards above their base of attachment, with the crown straight or very slightly curved, as in the posterior teeth. The premaxillary bone supports four small teeth; each superior maxillary bone has eight much larger ones, which gradually decrease in size as they are placed farther back. There are eight or nine teeth of similar size and proportions in each premandibular bone. These teeth are separated by wide intervals, from which other teeth similar to those in place have been detached. The base of each of the above teeth is extended transversely, compressed antero-posteriorly, and ankylosed to a shallow alveolus extending obliquely across the shallower alveolar groove. An affinity to the lizard tribes is manifested by the greater development of the outer as compared with the inner wall of the alveolar furrow.

The palatine teeth, of which there are three or four in each palatal bone, are as large as the superior maxillary ones, and are similarly attached. The pterygoid teeth, five or six in number, which complete the internal dental series on the roof of the mouth, are of smaller size, and gradually diminish as they recede backwards. In the interspaces of the fixed teeth in both these bones, the places of attachment of the shed teeth are always visible, so that the dental formula, if it included the vacated with the occupied sockets, would express a greater number of teeth than are ever in place and use at the same time. In the smaller species of boa, the premaxillary bone is edentulous. All the teeth have a lethal perfection of form for piercing. Their direction prevents the escape of the prey in which they are once fixed; while the separate and independent movement of each half of both upper and lower jaw, and of the dentigerous bones of the palate, allows of the different series of teeth being successively withdrawn and implanted in a more advanced position in the victim, which is thus gradually drawn into the gullet without the retaining force being unduly relaxed during any part of the engulphing process.

The Colubers, like other true serpents, have two longitudinal

¹ *Proceedings of the Geological Society*, Jan. 20, 1841, No. xx., p. 257.

² *Geological Transactions*, 2d series, vol. v., p. 345.

Teeth of
Reptiles.

rows of teeth on the roof of the mouth, extending along the palatines and pterygoids. The genus *Oligodon* appears to form the sole exception to this rule. In the *Dryinus nasutus*, M. Duvernoy has noticed a few small teeth on the transverse bone or external pterygoid, as well as on the internal pterygoid.

In certain genera of non-venomous serpents, as *Dryophis*, *Dipsas*, and *Bucephalus*, in which the superior maxillary teeth increase in size towards the posterior part of the bone, the large terminal teeth of the series are traversed along their anterior and convex side by a longitudinal groove. In the *Bucephalus capensis*, the two or three posterior maxillary teeth present this structure, and are much larger than the anterior teeth, or those of the palatine or premandibular series; they add materially, therefore, to the power of retaining the prey, and may conduct into the wounds which they inflict an acrid saliva, but they are not in connection with the duct of an express poison-gland. The long grooved fangs are either firmly fixed to the maxillary bones, or are slightly moveable, according to their period of growth; they are concealed by a sheath of thick and soft gum, and their points are directed backwards. The sheath always contains loose recumbent grooved teeth, ready to succeed those in place.

In most of the *Colembri* each maxillary and premandibular bone includes from twenty to twenty-five teeth; they are less numerous in the genera *Tortrix* and *Homalopsis*, and are reduced to a still smaller number in the poisonous serpents in the typical genera, of which the short maxillary bone supports only a single perforated fang.

The transition to these serpents, which was begun in the *Bucephali* and allied genera with grooved maxillary teeth, is completed by the poisonous serpents of the genera *Pelamis*, *Hydrophis*, *Elaps*, *Bungarus*, and *Hamadryas*; which latter genus, as its cervical integument can be expanded into a hood, constitutes an intermediate link between *Bungarus* and *Naja*.

The superior maxillary bone (fig. 38, *b*) diminishes in length with the decreasing number of teeth which it supports; the ectopterygoid bone elongates in the same ratio, so as to retain its position as an abutment against the shortened maxillary, and the muscles implanted into this ectopterygoid style communicate, through it, to the maxillary bone, the hinge-like movements backwards and forwards upon the ginglymoid articulations connecting that bone with the anterior frontal and palatal bones. As the fully-developed poison-fangs are attached by the same firm basal ankylosis to shallow maxillary sockets, which forms the characteristic mode of attachment of the simple or solid teeth, they necessarily follow all the movements of the superior maxillary bone. When the external pterygoid is retracted, the superior maxillary rotates backwards, and the poison-fang is concealed in the lax mucous gum with its point turned backwards; when the muscles draw forward the external pterygoid, the superior maxillary bone is pushed forwards, and the recumbent fang withdrawn from its concealment and erected.

In this power of changing the direction of a large tooth, so that it may not impede the passage of food through the mouth, we may perceive an analogy between the viper and the *Lophius*; but in the fish the movement is confined to the tooth alone, and is dependent on the mere physical property of the elastic medium of attachment; in the serpent, the tooth has no independent motion, but rotates with the jaw, whose movements are governed by muscular actions. In the fish, the great teeth are erect, except when pressed down by some extraneous force; in the serpent, the habitual position of the fang is the recumbent one, and its erection takes place only when the envenomed blow is to be struck.

A true idea of the structure of a poison-fang will be formed by supposing the crown of a simple tooth, as that of a boar, to be pressed flat, and its edges to be then bent towards each other, and soldered together so as to form a hollow cylinder open at both ends. The flattening of the fang, and its inflection around the poison-duct, commences immediately above the base, and the suture of the inflected margins runs along the anterior and convex side of the recurved fang: the poison canal is thus in front of the pulp-cavity. The basal aperture of the poison-canal is oblique, and its opposite outlet is more so, presenting the form of a narrow elliptical longitudinal fissure, terminating at a short distance from the apex of the fang.

The character most commonly adduced from the dental system, as distinguishing the venomous from the non-venomous serpents, is, that the former have two, the latter four, rows of teeth in the upper jaw, the two outer or maxillary rows being supplied by the single poison-fang. The exceptions to this rule are, however, too numerous for its value as a distinguishing character in a question of

Fig. 38.
Skull and Teeth of the Rattlesnake
(*Crotalus durissus*).

such practical moment as the venomous or non-venomous properties of a serpent. In all the family of marine serpents the poison-fang is only the foremost of a row of fixed maxillary teeth. In the *Hydrophis striatus*, e.g., there are four teeth, and in the *Hydrophis schistosa* there are five teeth behind the venom-fang, of rather smaller size than it; the two-coloured sea-snake (*Pelamis bicolor*) has also five maxillary teeth in addition to the perforated one. The poison-fang in this genus is relatively smaller than in the venomous serpents of the land, but presents the same peculiar structure, and death has followed the wound it has inflicted. The poison-glands occupy the sides of the posterior half of the head: each consists of a number of elongated narrow lobes, extending from the main duct, which runs along the lower border of the gland, upwards and slightly backwards; each lobe gives off lobules throughout its extent, thus presenting a pinnatifid structure; and each lobule is subdivided into smaller secreting caeca, which constitute the ultimate structure of the gland.

The whole gland is surrounded by a double aponeurotic capsule, of which the outermost and strongest layer is in connection with the muscles by whose contraction the several caeca and lobes of the gland are compressed and emptied of their secretion. This is then conveyed by the duct to the basal aperture of the poison-canal of the fang. We may suppose that, as the analogous lacrymal and salivary glands in other animals are most active during particular emotions, so the rage which stimulates the venom-snake to use its deadly weapon must be accompanied with an increased secretion and great distension of the poison-glands; and, as the action of the compressing muscles is contemporaneous with the blow by which the serpent inflicts its wound, the poison is at the same moment injected with force into the wound from the apical outlet of the perforated fang.

The duct which conveys the poison, although it runs through the centre of a great part of the tooth, is really on the outside of the tooth—the canal in which it is lodged and protected being formed by a longitudinal inflection of the parietes of the pulp-cavity, or true internal canal of the tooth. This inflection commences a little beyond the base of the tooth, where its nature is readily appreciated, as the poison-duct there rests in a slight groove or longitudinal indentation on the convex side of the fang; as it proceeds, it sinks deeper into the substance of the tooth, and the sides of the groove meet and seem to coalesce, so that the trace of the inflected fold ceases in some species to be perceptible to the naked eye, and the fang appears, as it is commonly described, to be perforated by the duct in the poison-fang.

From the real nature of the poison-canal it follows, that the transverse section of the tooth varies in form in different parts of the tooth. At the base it is oblong, with a large pulp-cavity of a corresponding form, with an entering notch at the anterior surface; farther on, the transverse section presents the form of a horse-shoe, and the pulp-cavity that of a crescent, the horns of which extend into the sides of the deep cavity of the poison-fang; a little beyond this part the section of the tooth is crescentic, with the horns obtuse and in contact, so as to circumscribe the poison-canal; and along the whole of the middle four-sixths of the tooth, the section shows the dentine of the fang inclosing the poison-cavity, and having its own centre or pulp-cavity *p*, in the form of a crescentic fissure, situated close to the concave border of the inflected surface of the tooth. It is such a section of which a magnified view is given in fig. 39. The pulp-cavity disappears, and the poison-canal again assumes the form of a groove near the apex of the fang, and terminates on the anterior surface in an elongated fissure.

The venom-fangs of the viper, rattlesnake, and fer-de-lance are coated only with a thin layer of a subtransparent and minutely-cellular cement; the disposition of the calcigerous tubes is obedient to the general law of verticality to the external surface of the tooth: it is represented, as seen in a transverse section from the middle of the fang, in fig. 39. Since the inflected surface of the tooth can be exposed to no other pres-

Rattlesnake.

Teeth of Reptiles.

sure than that of the turgescient duct with which it is in contact, the tubes which proceed to that surface, *v*, while maintaining their usual relation of the right angle to it, are extremely short, and the layer of dentine separating the poison-tube from the pulp-cavity *p* is proportionably thin. The dentinal tubes that radiate from the opposite side of the pulp-cavity to the exposed surface of the tooth *d* are disproportionately long.

The teeth of all Ophidians are developed and completed in that which is the original seat of the tooth-germs in all animals—viz., the mucous membrane or gum covering the alveolar border of the dentigerous bones. This gum presents the same lax tissue, and is as abundantly developed, as in the pike, *Iophius*, and many other fishes, in which it likewise serves as the nidus and locality for the complete development of the teeth.

The primitive dental papilla in the common harmless snake very soon sinks into the substance of the gum, and becomes inclosed by a capsule. As soon as the deposition of the calcareous salts commences in the apex of the papilla, the capsule covering that part becomes ossified and adherent to the dentine, and the tooth begins to pierce and emerge from the gums before its mould, the pulp, is half completed. Fresh layers of cells are successively added to the base of the pulp, and converted by their confluence and calcification into the tubular dentine, until the full size of the tooth is attained, when its situation in the gum is gradually changed, and its base becomes ankylosed to the shallow cavity of the alveolar surface of the bone.

In the posterior part of the large mucous sheath of the poison-fang, the successors of this tooth are always to be found in different stages of development: the pulp is at first a simple papilla, and when it has sunk into the gum, the succeeding portion presents a depression along its inferior surface, as it lies horizontally with the apex directed backwards. The capsule adheres to this inflected surface of the pulp; and the introduction of the duct of the poison-gland is completed by the extension of the borders of the inflected pulp around that tube.

Lacertia.

Among the inferior or squamate Saurians (lizards, monitors, iguanas) there are two leading modifications in the mode of attachment of the teeth, the base of which may be either ankylosed to the summit of an alveolar ridge, or to the bottom of an alveolar groove, and supported by its lateral wall; these modifications are indicated by the terms "acrodont" and "pleurodont." A third mode of fixation is presented by some extinct Saurians, which in other parts of their organization adhere to the squamate or lacertine division of the order,—the teeth being implanted in sockets, either loosely or confluent with the bony walls of the cavity: these may be termed the "theodont"¹ Lacertians. Most of the ancient triassic and permian Saurians belong to this group.

Varanidae.

In the crocodilian monitor-lizard (*Varanus crocodilinus*), the large fixed compressed teeth, of which there may be about seven in each upper maxillary bone, and six in each premandibular, are ankylosed by the whole of their base, and by an oblique surface leading upwards on the outer side of the tooth to a slight depression on the oblique alveolar surface, as in the variety called *striatus*. In this monitor the base of the tooth is finely striated, the lines being produced by inflected folds of the external cement, as in the *Ichthyosaurus* and *Labyrinthodon*, but being short and straight, as in those of the former genus.

The alveolar channel or groove has scarcely any depth; but the ankylosed base of the tooth is applied to an oblique surface, terminating in a sharp edge, from which the outer side of the free crown of the tooth is directly continued. The great *Varanus*, like the variegated species, manifests its affinity to the Crocodilians in the number of successive teeth which are in progress of growth to replace each other; but from the position in which the germs of the successional teeth are developed, the more advanced teeth in this species, as in the variety *variegatus*, do not exhibit the excavation that characterizes the same parts of the teeth of the *Enalliosaurs* and crocodile.

Dinosauria.

The compressed piercing and trenchant form of tooth which characterizes the varanian lizards was anciently manifested by a gigantic extinct Saurian, of which the remains were discovered by the late Dr Buckland in the oolitic slate of Stonesfield, near Oxford. These remains have been examined by the writer in the geological museum of that university. The specimen which is most illustrative of the dental peculiarities is a portion of the lower jaw with a few teeth. The first character which attracts the attention of the anatomist in this fossil is the inequality in the height of the outer and inner alveolar walls. This assures him of the saurian affinities of the gigantic reptile, a similar inequality characterizing the jaws of almost all the existing lizards. But in these the oblique groove, so bounded, to which the bases of the developed teeth are ankylosed, is much more shallow, and is relatively wider; and the

teeth in all the stages of growth are completely exposed when the gum has been removed.

Teeth of Reptiles.

In the great oolitic carnivorous lizard, which its discoverer has called *Megalosaurus*, the greater relative development of the inner alveolar wall, as compared with the dentigerous part of the jaw in existing Saurians, narrows the dental groove, and covers a greater proportion of the bases of the teeth, besides concealing more or less completely the germs of their successors. Moreover, instead of the mere shallow impressions upon the inner side of the outer alveolar plate to which the teeth are attached in modern lizards, there are distinct sockets formed by bony partitions connecting the outer with the inner alveolar wall in the jaw of the *Megalosaurus*. These partitions rise from the outer side of the inner alveolar wall in the form of triangular vertical plates of bone, and from the middle of the outer side of each plate a bony partition crosses to the outer parapet, completing the alveoli of the fully-formed or more advanced teeth; the series of triangular plates forming a kind of zig-zag buttress along the inner side of those alveoli. The outer parapet rises an inch higher than the inner one.

Of the fully-developed teeth, only one has been preserved *in situ* in the specimen under description; the others appear rather to have slipped out than to have been broken off, the ankyloses of the basal capsule of the tooth to the alveolar periosteum being but slight, and apparently taking place tardily, in the *Megalosaurus*.

Fig. 40 exhibits a portion of another jaw of the *Megalosaurus*, also

Teeth of
Reptiles.

to show the germ of a successional tooth *c*, about to succeed an old tooth *a*, which has been broken, and near to which is a newly-formed tooth coming into place *b*. These teeth well exemplify the shape of the crown of the tooth, which is subcompressed, slightly recurved, sharp-edged, and sharp-pointed, the edges being minutely serrated; the edge upon the convex or front border *b* becomes blunted as it descends about two-thirds of the way towards the base of the tooth; that upon the concave hinder border *a* is continued to the base. The lower half of the crown is thicker towards the fore margin than towards the hind one; so that a transverse section, like that above (*a*, in fig. 40), gives a narrow oval form pointed behind. At the upper half of the crown the sides slope more equally from the middle thickest part to both margins, and the section is a narrow pointed ellipse. The crown is covered by a smooth and polished enamel, which wholly forms the marginal serrations. The base of the tooth is coated with a smooth, lighter-coloured cement, forming a thin layer, and becoming a little thicker towards the implanted end of the tooth. The remains of the pulp are converted into osteodentine in the basal part of the completely formed tooth. Moderately magnified, the surface of the enamel presents a finely-wrinkled appearance. The marginal serrations show, under a somewhat higher power, that the points are directed towards the apex of the tooth—a structure well adapted for dividing the tough tissues of the saurian integument.

The main body of the tooth consists of dentine, of that hard unvascular kind of which the same part of the teeth of existing crocodiles and most mammals is composed. The dentinal tubules in the *Megalosaurus* are extremely fine and close-set, presenting a diameter of $\frac{1}{1000}$ of an inch, with interspaces varying between two and three times that diameter. They radiate from the pulp-cavity at right angles with the external surface of the tooth. The primary curvatures correspond with those of the dentinal tubules in the *Varanus* (figured in the author's *Odontography*, plate lxxvii., fig. 2), but they are less marked; so that the tubules appear straighter in the *Megalosaurus*. After their origin, they dichotomize sparingly, but the number of minute secondary branches sent off into the intermediate substance is very great. These secondary branches proceed at acute angles from the primary tubules; the divisions of the latter become very frequent near the periphery of the dentine, and the terminal branches dilate into, or inosculate with, a stratum of minute calcigerous cells, which separates the dentine from the enamel.¹ No part of the dentine is pervaded by medullary canals, as in the *Iguanodon*.

A series of teeth from individual *Megalosauri*, of different ages, are preserved in the British Museum and in the geological museum at Oxford; although differing in size, they preserve the characteristic form above described. In one specimen the point of the crown and the trenchant margins have been rubbed down to a smooth obtuse surface; it seems to have come from the hinder part of the dental series, where the teeth may have been smaller and less sharp, or more liable to be blunted by a greater share in the imperfect act of mastication, than the teeth in advance.

Successional teeth in different stages of growth are shown in the original portion of jaw of the *Megalosaurus* in the Oxford museum. Some, more advanced, show their crowns projecting from alveoli already formed by the plates extending across from the triangular processes before described. Vacant sockets, from which fully-formed teeth have escaped, occur, generally in the intervals between these more advanced teeth. The summits of less developed teeth are seen protruding at the inner side of the basal interspaces of the triangular plate, between them and the true internal alveolar parapet. There can be no doubt that, in the course of the development of these teeth, corresponding changes take place in the jaw itself, by which new triangular plates and alveolar partitions are formed, as the old ones become absorbed, analogous to those concomitant changes in the growth and form of the teeth, alveoli, and jaws which take place in so striking a degree in the elephant. The peculiarity of the *Megalosaurus*, as compared with the crocodiles and lizards, which have a like endless succession of teeth, is the deeper position of the successional tooth (fig. 40, *c*), in relation to the one (*a*) it is destined to replace, and the great proportion of the tooth which is formed before it is protruded. This interesting character is well exhibited in the portion of the jaw kindly submitted to the author's examination by the late Duke of Marlborough, and a portion of which is shown in fig. 40. The anterior tooth *a* in this specimen shows at the inner side of its base the commencing absorption stimulated by the encroaching capsule of the successional tooth *c* below, the crown of which is completed externally, though not consolidated. On one of the fractured margins of this piece of

jaw, a part of the basal shell of an absorbed and shed tooth remains, with part of the root of the successional tooth, which has risen into place, but which shows its base full of matrix, the pulp not having been calcified at that period of the tooth's growth.

In the proportion of the successional teeth which is formed in the formative cavity in the substance of the jaw, the *Megalosaurus* offers a closer resemblance to the mammalian class than do any of the recent or extinct crocodilian or lacertian reptiles. But the evidence of uninterrupted and frequent succession of the teeth in the *Megalosaurus* is unequivocal; and this part of the dental economy of the great carnivorous reptile is strictly analogous to that which governs the same system in the existing members of the class. The different forms of the teeth at different stages of protrusion did not fail to attract the attention of the gifted discoverer of the *Megalosaurus*, in whose words this notice of its dentition may be fitly concluded:—

"In the structure of these teeth we find a combination of mechanical contrivances analogous to those which are adopted in the construction of the knife, the sabre, and the saw. When first protruded above the gum, the apex of each tooth presented a double cutting edge of serrated enamel. In this stage its position and line of action were nearly vertical; and its form, like that of the two-edged point of a sabre, cutting equally on each side. As the tooth advanced in growth, it became curved backwards in the form of a pruning-knife, and the edge of serrated enamel was continued downwards to the base of the inner and cutting side of the tooth, whilst on the outer side a similar edge descended, but a short distance from the point; and the convex portion of the tooth became blunt and thick, as the back of a knife is made thick for the purpose of producing strength. The strength of the tooth was further increased by the expansion of its side. Had the serrature continued along the whole of the blunt and convex portion of the tooth, it would in this position have possessed no useful cutting power; it ceased precisely at the point beyond which it could no longer be effective. In a tooth thus formed for cutting along its concave edge, each movement of the jaw combined the power of the knife and saw; whilst the apex, in making the first incision, acted like the two-edged point of a sabre. The backward curvature of the full-grown teeth enabled them to retain, like barbs, the prey which they had penetrated. In these adaptations we see contrivances which human ingenuity has also adopted in the preparation of various instruments of art."²

The lizards of the Iguanian family are characterized by a short Iguanidæ contractile tongue, slightly notched at its extremity, but are distinguished for the most part by having teeth on the pterygoid bone, and also by the complicated form of the crown of the maxillary teeth in the typical genera, the species of which subsist chiefly on vegetable substances. In most of the Iguanians the teeth are lodged in a common shallow, oblique, alveolar groove, and are soldered to excavations on the inner surface of the outer wall of the groove.

In the pleurodont Iguanians, the teeth never present the true lanian form; and if simply conical, as at the extremes of the maxillary series, the cone is more or less obtuse; but in general it is expanded, more or less trilobate, or dentated along the margins of the crown.

The dentition of the Basilisks differs little from that of the Iguanæ. The posterior teeth are rather trilobate than tricuspid; the anterior ones are small, circular, pointed, and slightly curved. There are generally from five to six conical teeth on each pterygoid bone; but in the mitred Basilisk there are twelve teeth in each of these rows.

The *Amblyrhynchus*, a genus which is somewhat remarkable for the marine habits of at least one of the species (*Amblyrhynchus ater*), whose diet is sea-weed, has the tricuspid structure well developed in the posterior teeth.

The typical genus of the present family of Saurians is characterized by the crenate or dental margin of the crown of the maxillary and premandibular teeth, a few of the anterior small ones excepted. The pterygoid teeth are arranged in two or three irregular rows, resembling somewhat the *dents en cardes* of fishes.

In the full-grown horned Iguana (*Metopoceros cornutus*, Dum.), there are about fifty-six teeth in both the upper and lower jaws, of which the four first are conical and slightly recurved; the twelve succeeding teeth are somewhat larger in size, with more compressed and expanded crowns; the rest are triangular, compressed, with dentated margins. The inner surface of the crown of the tooth is simply convex and smooth, the outer surface traversed by a median longitudinal, broad, obtuse ridge. Fig. 41 gives a view of these teeth on the inner side of the lower jaw: *a*, the teeth in place, ankylosed to the outer parapet of the alveolar groove; *b*, the germ

Teeth of
Reptiles.

² Buckland, *Bridgewater Treatise*, vol. i., p. 237.

Teeth of Reptiles. of a successional tooth; c, a tooth more advanced, and rising into place. The base of the older teeth soon begins to be sapped by the absorbent process excited by the pressure of the capsules of their

racters peculiar to that genus. In most of the teeth that have hitherto been found, three longitudinal ridges traverse the outer surface of the crown, one on each side of the median primitive

Teeth of Reptiles.

Fig. 41.
Lower Jaw and Teeth of an Iguana (*Metopoceros cornutus*).

successors. In the common as in the horned iguana there is a single row of small teeth implanted in each pterygoid bone; but no iguanian lizard has teeth on the palatine bones.

The pulp-cavity in old teeth becomes occupied by a coarse bone, characterized by large irregularly-shaped calciferous cells; and the interspaces are filled with irregular moss-like reticulations of tubes. Branches of the pulp-cavity are never continued in the form of medullary canals into the substance of the dentine in the existing Iguanae.

The germs of the successional teeth (b, fig. 41), are developed from the mucous membrane covering the inner side of the base of those in place. The apex of the dentated crown is first formed; by its pressure it excites absorption of the base of the fixed tooth, and soon undermines it, and then occupies the recess in the alveolar plate in the interspace of the two adjoining fixed teeth. After the crown is completed, the rest of the tooth forms a contracted and elongated fang, which at first is hollow, then becomes consolidated by ossification of the remaining pulp c, and is afterwards a second time excavated by the pressure of a new tooth.

Dinosauria. The value of a knowledge of the comparative anatomy of the teeth, and especially of their external characters, in the cold-blooded classes of animals, has never, perhaps, been placed in so striking a point of view as in the leading steps to the discovery of the present most extraordinary and gigantic reptile. The detached teeth and bones of the *Iguanodon*, successively discovered in the Wealden strata of Sussex, and afterwards found associated together to the extent of nearly half the skeleton of one and the same individual, in the greensand of Kent, offer not the least marvellous or significant evidences of the inhabitants of the now temperate latitudes during the later secondary periods of the formation of the earth's crust.

With vertebrae, subconcave at both articular extremities, having, in the dorsal region, lofty and expanded neural arches, and doubly articulated ribs, and characterized in the sacral region by their unusual number and complication of structure; with a Lacertian pectoral arch, and unusually large bones of the hind limbs, excavated by large medullary cavities, and adapted for terrestrial progression;—the *Iguanodon* was distinguished by teeth, resembling in shape those of the Iguana, but in structure differing from the teeth of that and every other known reptile, and unequivocally indicating the former existence in the Dinosaurian order of a gigantic representative of the small group of living lizards which subsist on vegetable substances.

The important difference which the fossil teeth presented in the form of their grinding surface was pointed out by Cuvier,¹ of whose description Dr Mantell adopted a condensed view in his *Illustrations of the Geology of Sussex*, 4to, 1827, p. 72. The combination of this dental distinction with the vertebral and costal characters, which prove the *Iguanodon* not to have belonged to the same group of Saurians as that which includes the Iguana and other modern lizards, rendered it highly desirable to ascertain by the improved modes of investigating dental structure, the actual amount of correspondence between the *Iguanodon* and Iguana in this respect. This has been done in the author's general description of the teeth of reptiles,² from which the following notice is abridged:—

The teeth of the *Iguanodon* (fig. 42), though resembling most closely those of the Iguana, do not present an exact magnified image of them, but differ in the greater relative thickness of the crown, its more complicated external surface, and, still more essentially, in a modification of the internal structure, by which the *Iguanodon* equally deviates from every other known reptile.

As in the Iguana, the base of the tooth is elongated and contracted; the crown expanded and smoothly convex on the inner side; when first formed it is acuminate, compressed, its sloping sides serrated, and its external surface traversed by a median longitudinal ridge, and coated by a layer of enamel; but beyond this point the description of the tooth of the *Iguanodon* indicates cha-

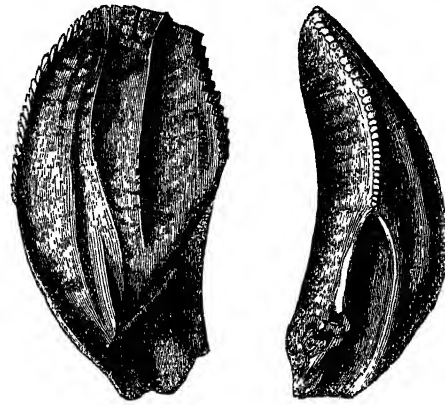

Fig. 42.
Front and side views of a Tooth of the *Iguanodon*, nat. size.

ridge; these are separated from each other and from the serrated margins of the crown by four wide and smooth longitudinal grooves. The relative width of these grooves varies in different teeth; sometimes a fourth small longitudinal ridge is developed on the outer side of the crown. The marginal serrations which, at first sight, appear to be simple notches, as in the Iguana, present under a low magnifying power (fig. 43), the form of transverse ridges, themselves notched, so as to resemble the mammillated margins of the unworn plates of the elephant's grinder; slight grooves lead from the interspaces of these notches upon the sides of the marginal ridges. These ridges or dentations do not extend beyond the expanded part of the crown; the longitudinal ridges are continued farther down, especially the median ones, which do not subside till the fang of the tooth begins to assume its sub-cylindrical form. The tooth at first increases both in breadth and thickness; then it diminishes in breadth, but its thickness goes on increasing; in the larger and fully formed teeth, the fang decreases in every diameter, and sometimes tapers almost to a point. The smooth unbroken surface of such fangs indicates that they did not adhere to the inner side of the maxillae, as in the Iguana, but were placed in separate alveoli, as in the Crocodile and Megalosaur; such support would appear, indeed, to be indispensable to teeth so worn by mastication as those of the *Iguanodon*.

Fig. 43.
Marginal ridges on the Tooth of the *Iguanodon*, magn.

The apex of the tooth soon begins to be worn away, and it would appear, by many specimens, that the teeth were retained until nearly the whole of the crown had yielded to the daily abrasion. In these teeth, however, the deep excavation of the remaining fang plainly bespeaks the progress of the successional tooth prepared to supply the place of the worn-out grinder. At the earlier stages of abrasion a sharp edge is maintained at the external part of the tooth by means of the enamel which covers that surface of the crown; the prominent ridges upon that surface give a sinuous contour to the middle of the cutting edge, whilst its sides are jagged by the lateral serrations. The adaptation of this admirable dental instrument to the cropping and comminution of such tough vegetable food as the *Clathraria* and similar plants, which are found buried with the *Iguanodon*, is pointed out by Dr Buckland, with his usual felicity of illustration, in his *Bridgewater Treatise*, vol. i., p. 246.

When the crown is worn away beyond the enamel, it presents a broad and nearly horizontal grinding surface (fig. 44), and now another dental substance is brought into use, to give an inequality to that surface; this is the ossified remnant of the pulp, which, being firmer than the surrounding dentine, forms a slight transverse ridge in the middle of the grinding surface; the tooth in this stage has exchanged the functions of an incisor for that of a molar, and is prepared to give the final compression, or comminution, to the coarsely divided vegetable matters.

The marginal edge of the incisive condition of the tooth and the median ridge of the molar stage are more effectually established by the introduc-

Teeth of Reptiles.

tion of a modification into the texture of the dentine, by which it is rendered softer than in the existing *Iguanæ* and other reptiles, and more easily worn away. This is effected by an arrest of the calcifying process along certain cylindrical tracts of the pulp, which is thus continued, in the form of medullary canals, analogous to those in the soft dentine of the *Megatherium's* grinder, from the central cavity, at pretty regular intervals, parallel with the dental tubes, nearly to the surface of the tooth. The medullary canals radiate from the internal and lateral sides of the pulp-cavity, and are confined to the dentine forming the corresponding walls of the tooth. Their diameter is $\frac{1}{1250}$ th of an inch. They are separated by pretty regular intervals equal to from six to eight of their own diameters. They sometimes divide once in their course. Each medullary canal is surrounded by a clear space. Its cavity was occupied in the section described by a substance of a deeper yellow colour than the rest of the dentine.

The dental tubes present a diameter of $\frac{1}{25,000}$ th of an inch, with interspaces equal to about four of their diameters. At the first part of their course, near the pulp-cavity, they are bent in strong undulations, but afterwards proceed in slight and regular primary curves, or in nearly straight lines to the periphery of the tooth. The secondary undulations of each tooth are regular, and very minute. The branches, both primary and secondary, of the dental tubes are sent off from the concave side of the main inflexions; the minute secondary branches are remarkable at certain parts of the tooth for their flexuous ramifications, anastomoses, and dilations into minute calcigerous cells, which take place along nearly parallel lines for a limited extent of the course of the main tubes. The appearance of interruption in the course of the dental tubes, occasioned by this modification of their secondary branches, is represented by the irregularly dotted tracts in the figure. This modification must contribute, with the medullary canals, though in a minor degree, in producing that inequality of texture and of density in the dentine, which renders the broad and thick tooth of the *Iguanodon* more efficient as a triturating instrument.

The enamel which invests the harder dentine, forming the outer side of the tooth, presents the same peculiar dirty brown colour, when viewed by transmitted light, as in most other teeth. Very minute and scarcely perceptible undulating fibres, running vertically to the surface of the tooth, form the only discernible structure in it.

The remains of the pulp in the contracted cavity of the completely formed tooth are converted into a dense but true osseous substance, characterized by minute elliptical radiated cells, whose long axis is parallel with the plane of the concentric lamellæ, which surround the few and contracted medullary canals in this substance.

The microscopical examination of the structure of the *Iguanodon's* teeth thus contributes additional evidence of the perfection of their adaptation to the offices to which their more obvious characters had indicated them to have been destined.

To preserve a trenchant edge, a partial coating of enamel is applied; and, that the thick body of the tooth might be worn away in a more regularly oblique plane, the dentine is rendered softer as it recedes from the enamelled edge, by the simple contrivance of arresting the calcifying process along certain tracts of the inner wall of the tooth. When attrition has at length exhausted the enamel, and the tooth is limited to its function as a grinder, a third substance has been prepared in the ossified remnant of the pulp to add to the efficiency of the dental instrument in its final capacity. And if the following reflections were natural and just, after a review of the external characters of the dental organs of the *Iguanodon*, their truth and beauty become still more manifest as our knowledge of their subject becomes more particular and exact:—

"In this curious piece of animal mechanism we find a varied adjustment of all parts and proportions of the tooth, to the exercise of peculiar functions, attended by compensations adapted to shifting conditions of the instrument during different stages of its consumption. And we must estimate the works of nature by a different standard from that which we apply to the productions of human art, if we can view such examples of mechanical contrivance, united with so much economy of expenditure, and with such anticipated adaptations to varying conditions in their application, without feeling a profound conviction that all this adjustment has resulted from design and high intelligence."¹

Dicynodon. The existing species of lizard differ from those of the crocodile in the anchylosed condition of the teeth, which present few modifications of importance; those that yield most fruit to physiology, and which have most expanded our ideas of the extent of the resources and exceptional deviations from what was deemed the rule of structure in the Saurian dentition, have been discovered by the

study of the fossil teeth of extinct forms of the order. Amongst these the most extraordinary, in respect of their dental system, have been recently discovered in a probably "Permian" formation in South Africa. These fossil reptiles have been termed "*Dicynodonts*," from their dentition being reduced to one long and large canine tooth on each side of the upper jaw, and these teeth impart, at first sight, a character to the jaws like that which the long poison-fangs give, when erected, to the jaws of the rattlesnake. Fig. 45 is a reduced side view of the skull and teeth of the

Teeth of Reptiles.

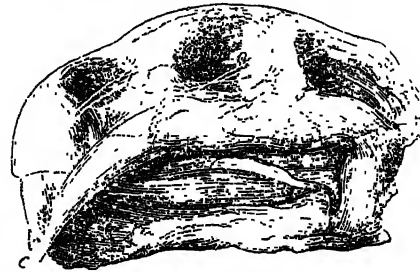

Fig. 45.

Skull and Tusks of *Dicynodon lacerticeps*.

Dicynodon lacerticeps. The maxillary bone is excavated by a wide and deep alveolus, with a circular area of half an inch, and lodges a long and strong, slightly curved, and sharp-pointed canine tooth or tusk *c*, which projects about two-thirds of its length from the open extremity of the socket. The direction of the tusks is forwards, downwards, and very slightly inwards; the two converging in the descent along the outer side of the compressed symphysis of the lower jaw. The tusk is principally composed of a body of compact unvascular dentine. The base is excavated by a wide conical pulp-cavity, with the apex extending to about one-half of the implanted part of the tusk, and a linear continuation extending along the centre of the solid part of the tusk. From this central line the dental tubes radiate, with a gentle curve at the beginning, convex towards the point of the tusk, and then proceeding straight to the periphery of the tooth, but inclining towards the apex. They present parallel secondary curves, divide dichotomously twice or thrice near their beginning, and send off numerous small lateral branches, chiefly from the side next the apex. At their primary curve the dental tubes are $\frac{1}{1250}$ th of an inch in diameter, and their intervals are $\frac{1}{2500}$ th of an inch across. The dental cells are most conspicuous near the periphery of the tooth, and vary in diameter from $\frac{1}{8000}$ th to $\frac{1}{10000}$ th of an inch.

The enamel, at least at the middle of the tusk, is thinner than in the teeth of the crocodile. It presents only a finely lamellated texture, the layers being parallel with the surface of the dentine on which it rests. There is only a fine linear trace of cement on the exterior of the sections of the implanted base of the tusks; and here it is too thin to allow of the development of the radiated cells in its substance. There is no trace of teeth or their sockets in the lower jaw,² so much of the alveolar border as is exposed presents a smooth and even edge, which seems to have played like a scissor-blade upon the inner side of the corresponding edentulous border of the upper jaw; and it is most probable, from the analogies of similarly-shaped jaws of existing reptilia, that the fore-part of both the upper and under jaws were sheathed with horn.

Until the discovery of the *Rhynchosaurus*, this edentulous and horn-sheathed condition of the jaws was supposed to be peculiar to the chelonian order among reptiles; and it is not one of the least interesting features of the *Dicynodonts* of the African sandstones, that they should repeat a chelonian character hitherto peculiar amongst *Lacertians*, to the above-cited remarkable extinct edentulous genus of the new red sandstone of Shropshire; but our interest rises almost to astonishment, when, in a saurian skull, we find, superadded to the horn-clad mandibles of the tortoise, a pair of tusks, borrowed, as it were, from the mammalian class, or rather foreshadowing a structure which, in the existing creation, is peculiar to certain members of the highest organized warm-blooded animals.

Crocodylia.—The ancient writers on natural history appear to have been much struck with the great number of teeth in the crocodile; and their descriptions were exaggerated to the tone of the impressions thus produced. Thus, according to Achilles Tatius, the crocodile had as many teeth as there were days in the year.

How many teeth a crocodile may develop through the whole course of its life in uninterrupted succession, will never, perhaps, be determined; they then would doubtless far exceed in number the liberal allowance of Tatius; but with regard to those teeth which are in use in the jaws at any given time, the number is now

¹ Buckland's *Bridgewater Treatise*, vol. i., p. 249.² *See*, two, *κενέδους*, canine tooth.

Teeth of Reptiles.

well established—e.g., the crocodile of the Nile has $\frac{17-17}{16-16}=66$; that of the West Indies (*Crocodilus acutus*) has $\frac{17-17}{16-16}=66$; the common alligator (*Aligator lucius*), has $\frac{20-20}{18-18}=76$. The great gavia or garrhial (*Gavalis Gangeticus*) has $\frac{30-30}{20-20}=778$. Thus the different species and genera of crocodiles differ from each other in the number of teeth, and also the individuals differ within small limits.

The best and most readily recognisable characters by which the existing Crocodilians are grouped in appropriate genera are derived from modifications of the dental system.

In the caimans (genus *Alligator*) the teeth vary in number from 18—18 to 22—22; the fourth tooth of the lower jaw or canine, is received into a cavity of the palatal surface of the upper jaw, where it is concealed when the mouth is shut; in old individuals the upper jaw is perforated by these large inferior canines, and the fossæ are converted into foramina.

In the true crocodiles (genus *Crocodilus*) the first tooth in the lower jaw perforates the palatal process of the intermaxillary bone when the mouth is closed; the fourth tooth in the lower jaw is received into a notch excavated in the side of the alveolar border of the upper jaw, and is visible externally when the mouth is closed.

In the two preceding genera the alveolar borders of the jaws have an uneven or wavy contour, and the teeth are of unequal size.

In the gavials (genus *Gavialis*) the teeth are nearly equal in size and similar in form in both jaws, and the first as well as the fourth tooth in the lower jaw passes into a groove in the margin of the upper jaw, when the mouth is closed.

The number of teeth is always greater in the gavials than in the crocodiles or alligators. The first five pairs of teeth above are supported by the premaxillary bones; the first, second, and fourth of the lower jaw are the longest.

The eight or nine posterior teeth are nearly conical, the rest are sub-compressed antero-posteriorly, and present a trenchant edge on the right and left side, between which a few faint longitudinal ridges traverse the basal part of the enamelled crown (fig. 46).

The position of the opposite sharp ridges, and the direction of the flat sides of the crown, are reversed in the extinct crocodile (*Croc. cultridens*), which in other respects most nearly resembles the gavia in the form of the teeth.

In most of the extinct species of Crocodilians the teeth are characterized by more numerous and strongly developed longitudinal ridges upon the enamelled crown, than in the recent species; and they are commonly longer, more slender, and sharp-pointed. But in one of the crocodiles with sub-biconcave vertebræ (*Goniopholis crassidens*), from the Wealden formation and Purbeck limestone, the teeth have crowns which are as round and as thick in proportion to their length as in the recent crocodiles or alligators.

The more ancient crocodiles, from the Oolite and Lias, called *Stenosaurs* and *Telosaurus*, had jaws like those of the modern gavials, but sometimes longer and more attenuated, and armed with more numerous, equal, and slender teeth, adapted for the capture of fishes, which appear to have been the only other vertebrate animals existing at those periods in numbers sufficient to yield subsistence to carnivorous marine Saurians.

In all the *Telosaurus* the teeth are more slender, less compressed, and sharper pointed than in the gavia; they are slightly recurved, and the enamelled crown is traversed by more numerous and better defined ridges—two of which, on opposite sides of the crown, are larger and more elevated than the rest. The fang is smooth, cylindrical, and always excavated at the base. The teeth of the *Stenosaurs*, or extinct crocodiles with long and slender jaws, and with vertebræ sub-concave at both extremities, but with subterminal nostrils, differ from those of the *Telosaurus* in being somewhat thicker in proportion to their length, and larger in proportion to the jaws.

The teeth of both the existing and extinct crocodilian reptiles consist of a body of compact dentine, forming a crown covered by a coat of enamel, and a root invested by a moderately thick layer of cement. The root slightly enlarges or maintains the same breadth to its base (fig. 46, a), which is deeply excavated by a conical pulp-cavity extending into the crown, and is commonly either perforated or notched at its concave or inner side.

In the black alligator of Guiana, the first fourteen teeth in the lower jaw are implanted in distinct sockets. The remaining posterior teeth

are lodged close together in a continuous groove, in which the divisions for sockets are faintly indicated by vertical ridges, as in the jaws of the Ichthyosaurus.

A thin compact floor of bone separates this groove and the sockets anterior to it (fig. 47) from the large cavity of the ramus of the jaw. It is pierced by blood-vessels for the supply of the pulps of the growing teeth and the vascular dentigerous membrane which lines the alveolar cavities.

The tooth-germ c (fig. 47) is developed from the membrane covering the angle between the floor and the inner wall of the socket. It becomes, in this situation, completely enveloped by its capsule, and partially calcified, before the young tooth penetrates the interior of the pulp-cavity of its predecessor.

The matrix of the young growing tooth affects, by its pressure, the inner wall of the socket, as shown in fig. 47, and forms for itself a shallow recess, at the same time it attacks the side of the base of the contained tooth; then, gaining a more extensive attachment by its basis and increased size, it penetrates the large pulp-cavity of the previously formed tooth either by a circular or semi-circular perforation. The size of the perforation in the tooth, and of the depression in the jaw, proves them to have been in great part caused by the soft matrix, which must have produced its effect by exciting absorbent action, and not by mere mechanical force. The resistance of the wall of the pulp-cavity having been thus overcome, the growing tooth and its matrix recede from the temporary alveolar depression, and sink into the substance of the pulp contained in the cavity of the fully-formed tooth.

As the new tooth grows, the pulp of the old one is removed; the old tooth itself is next attached, and the crown, being undermined by the absorption of the inner surface of its base, may be broken off by a slight external force, when the point of the new tooth is exposed, as in figs. 46 and 47, b.

The new tooth disengages itself of the cylindrical base of its predecessor (fig. 47, a) with which it is sheathed, by maintaining the excitement of the absorbent process so long as the cement of the old fang retains any vital connection with the periosteum of the socket; but the frail remains of the old cylinder, thus reduced, are sometimes lifted out of the socket upon the crown of the new tooth (as in fig. 46, a), when they are speedily removed by the action of the jaws. This is, however, the only part of the process which is immediately produced by violence; an attentive observation of the more important previous stages of growth, teaches that the pressure of the growing tooth operates upon the one to be displaced only through the medium of the vital absorbent action which it has excited.

Most of the stages in the development and succession of the teeth of the crocodiles are described by Cuvier with his wonted clearness and accuracy; but the mechanical explanation of the expulsion of the old teeth, which Cuvier adopts from M. Tenon, is opposed by the disproportion of the hard part of the new tooth to the vacuity in the walls of the old one, and by the fact that the matter impressing, viz., the uncalcified part of the tooth matrix, is less dense than the part impressed.

No sooner has the young tooth (fig. 46, b) penetrated the interior of the old one (fig. 46, a) than another germ c, begins to be developed from the angle between the base of the young tooth and the inner alveolar process; or in the same relative position as that in which its predecessor began to rise, and the processes of succession and displacement are carried on uninterruptedly throughout the long life of these cold-blooded carnivorous reptiles.

From the period of exclusion from the egg, the teeth of the crocodile succeed each other in the vertical direction; none are added from behind forwards like the true molars in Mammalia. It follows, therefore, that the number of the teeth of the crocodile is as great when it first sees the light as when it has acquired its full size; and, owing to the rapidity of their succession, the cavity at the base of the fully-formed tooth is never consolidated.

The fossil jaws of the extinct Crocodilians demonstrate that the same law regulated the succession of the teeth at the ancient epochs when those highly-organised reptiles prevailed in greatest numbers, and under the most varied generic and specific modifications, as at the present period, when they are reduced to a single family composed of so few and slightly varied species as to have constituted in the system of Linnæus a small fraction of the genus *Lacerta*.

SECT. III.—TEETH OF MAMMALS.

The class *Mammalia*, like that of *Reptilia* and *Pisces*, includes a few genera and species that are devoid of teeth; the true ant-eaters (*Myrmecophaga*), the scaly ant-eaters, or Pangolins (*Manis*), and the spiny monotrematous ant-eater (*Echidna*), are examples of strictly edentulous Mammals. The *Ornithorhynchus* has horny teeth, and the whales (*Balæna* and *Balænoptera*) have transitory embryonic calcified teeth (fig. 59), succeeded by whale-bone substitutes (fig. 58), in the upper jaw. Horny processes analogous to, perhaps homologous with, the lingual and palatal teeth in fishes, are present in the *Echidna*. The female Narwhal seems to be edentulous, but has the germs of two tusks in the substance of the upper jaw-bones (fig. 62); one of these becomes developed into a large and conspicuous weapon in the male Narwhal (fig. 62, A), and accordingly suggested to Linnaeus the name, for its genus, of *Monodon*, meaning single tooth. But the tusk is never median, like the truly single tooth on the palate of the Myxine; and occasionally both tusks are developed in the Narwhal. In another Cetacean—the great Bottle-nose or *Hyperoodon*—the teeth are reduced in the adult to two in number (fig. 61), whence the specific name, *H. bidens*; but they are confined to the lower jaw. The sharp-nosed dolphin (*Ziphius*) has also but two teeth, one in each ramus of the lower jaw; and this is perhaps a sexual character.

The *Delphinus griseus* has five teeth on each side of the lower jaw; but they soon become reduced to two. Amongst the Marsupial animals, the genus *Tarsipes* is remarkable for the paucity as well as minuteness of its teeth. The Elephant has never more than one entire molar, or parts of two, in use on each side of the upper and lower jaws, to which are added two tusks, more or less developed, in the upper jaw.

Some Rodents, as the Australian water-rats (*Hydromys*), have two grinders on each side of both jaws, which, added to the four cutting teeth in front, make twelve in all; the common number of teeth in this order is twenty; but the hares and rabbits have twenty-eight teeth. The Sloth has eighteen teeth. The number of teeth, thirty-two, which characterizes man, the apes of the old world, and the true Ruminants, is the average one of the class *Mammalia*; but the typical number is forty-four.

The examples of excessive number of teeth are presented, in the order *Bruta*, by the Priodont Armadillo, which has ninety-eight teeth; and in the Cetaceous order by the Cachalot, which has upwards of sixty teeth, though most of them are confined to the lower jaw; by the common porpoise, which has between eighty and ninety teeth; by the Gangetic dolphin, which has one hundred and twenty teeth; and by the true dolphins (*Delphinus*), which have from one hundred to one hundred and ninety teeth, yielding the maximum number in the class *Mammalia*.

Where the teeth are in excessive number, as in the species above cited, they are small, equal, or sub-equal, and of a simple conical form; pointed, and slightly recurved in the common dolphin; with a broad and flattened base in the Gangetic dolphin; with the crown compressed, and broadest in the porpoise; compressed, but truncate, and equal with the fang, in the Priodon. The compressed triangular teeth become coarsely notched or dentated at the hinder part of the series in the great extinct cetaceous *Zeuglodon*. The simple dentition of the smaller Armadillos, of the Orycterope, and of the three-toed Sloth, presents a difference in the size, but little variety in the shape of the teeth, which are subcylindrical, with broad tritu-

rating surfaces; in the two-toed Sloth, the two anterior teeth of the upper jaw are longer and larger than the rest, and adapted for piercing and tearing.

Teeth are fixed, as a general rule, in all *Vertebrata*, and the only known exceptions are those presented by certain species of fishes; e. g., the Sharks, Lophioids, Goniodonts. In the higher *Vertebrata* the movements of the teeth depend on those of the jaw-bones to which they are affixed, but appear to be independent in the ratio of the size of the tooth to the bone to which it is attached. Thus the extent of rotatory movement to which the large perforated poison-fangs of the rattle-snake are subject, depends upon the rotation of the small maxillary bone; so, likewise, the seemingly individual movements of divarication and approximation observable in the large lower incisors of the *Bathyergus* and *Macropus*,¹ are due entirely to the yielding nature of the symphysis uniting the two rami of the lower jaw, in which those incisors are deeply and firmly implanted.

In man, where the premaxillaries early coalesce with the maxillary bones, where the jaws are very short, and the crowns of the teeth are of equal length, there is no interspace or "diastema" in the dental series of either jaw, and the teeth derive some additional fixity by their close apposition and mutual pressure. No inferior Mammal now presents this character; but its importance, as associated with the peculiar attributes of the human organization, has been somewhat diminished by the discovery of a like contiguous arrangement of the teeth in the jaws of a few extinct quadrupeds; e. g., *Anoplotherium*, *Nesodon*, and *Dichodon*.

The teeth in the *Mammalia*, as in the foregoing classes, are formed by superaddition of the hardening salts to pre-existing moulds of animal pulp or membrane, organized so as to insure the arrangement of the earthy particles according to that pattern which characterizes each constituent texture of the tooth. Development

The complexity of the primordial basis, or matrix, corresponds, therefore, with that of the fully-formed tooth, and is least remarkable in those conical teeth which consist only of dentine and cement. The primary pulp, which first appears as a papilla rising from the free surface of the alveolar gum, is the part of the matrix which, by its calcification, constitutes the dentine. In the simple teeth, the secondary, or enamel pulp, covers the dentinal pulp like a cap; in the complex teeth it sends processes into depressions of the coronal part of the dentinal pulp, which vary in depth, breadth, direction, and number, in the different groups of the herbivorous and omnivorous quadrupeds. The dentinal pulp, thus penetrated, offers corresponding complications of form; and, as the capsule follows the enamel pulp in all its folds and processes, the external cavities or interspaces of the dentine become occupied by enamel and cement—the cement, like the capsule which formed it, being the outermost substance, and the enamel being interposed between it and the dentine. The dental matrix presents the most extensive interdigitation of the dentinal and enamel pulps in the Capybara and Elephant. The matrix of the mammalian tooth sinks into a furrow, and soon becomes inclosed in a cell in the substance of the jaw-bone, from which the crown of the growing tooth extricates itself by exciting the absorbent process, whilst the cell is deepened by the same process, and by the growth of the jaw, into an alveolus for the root of the tooth. Where the formative parts of the tooth are reproduced indefinitely, to repair, by their progressive calcification, the waste to which the working surface of the crown of the tooth has been sub-

Teeth of
Mammals.

¹ See Mason Good's *Book of Nature*, vol. i. p. 285. 1826.

Teeth of
Mammals.

ject, the alveolus is of unusual depth, and of the same form and diameter throughout, except in the immature animal, when it widens to its bottom or base. In teeth of limited growth, the dentinal pulp is reproduced in progressively decreasing quantity after the completion of the exterior wall of the crown, and forms, by its calcification, one or more roots or fangs, which taper, more or less rapidly, to their free extremity. The alveolus is closely moulded upon the implanted part of the tooth; and it is worthy of special remark, that the complicated form of socket which results from the development of two or more fangs, is peculiar to animals of the class *Mammalia*.

In the formation of a single fang, the activity of the reproductive process becomes enfeebled at the circumference, and is progressively contracted within narrower limits in relation to a single centre, until it ceases at the completion of the apex of the fang, which, though for a long time perforated for the admission of the vessels and nerves to the interior of the tooth, is, in many cases, finally closed by the ossification of the remaining part of the capsule.

When a tooth is destined to be implanted by two or more fangs, the reproduction of the pulp is restricted to two or more parts of the base of the coronal portion of the pulp, around the centre of which parts the sphere of its reproductive activity is progressively contracted. The intervening parts of the base of the coronal pulp adhere to the capsule, which is simultaneously calcified with them, covering those parts of the base of the crown of the tooth with a layer of cement. The ossification of the surrounding jaw, being governed by the changes in the soft but highly organized dental matrix, fills up the spaces unoccupied by the contracted and divided pulp, and affords, by its periosteum, a surface for the adhesion of the cement or ossified capsule covering the completed part of the tooth.

The matrix of certain teeth does not give rise, during any period of their formation, to the germ of a second tooth, destined to succeed the first. This, therefore, when completed and worn down, is not replaced; all the true *Cetacea* are limited to this simple provision of teeth. In the *Armadillos*, *Megatherioids*, and *Sloths*, the want of germinative power, as it may be called, in the matrix, is compensated by the persistence of the matrix, and by the uninterrupted growth of the teeth. In most other *Mammalia*, the matrix of the first developed tooth gives origin to the germ of a second tooth, which sometimes displaces, sometimes takes its place by the side of, its predecessor and parent. All those teeth which are displaced by their progeny are called temporary, deciduous, or milk teeth (fig. 17, *d-i-d*, 4). The mode and direction in which they are displaced and succeeded, viz., from below upwards in the lower jaw, in both jaws vertically, are the same as in the crocodile; but the process is never repeated more than once in any mammiferous animal. A considerable proportion of the dental series is thus changed; the second, or permanent teeth (fig. 17, *i-l-p*, 4), having a size and form as suitable to the jaws of the adult as the displaced temporary teeth were adapted to those of the young animal.

The permanent teeth (fig. 17, *m-l-m*, 3), which assume places not previously occupied by deciduous ones, are always the most posterior in their position, and generally the most complex in their form. The successors of the deciduous incisors and canines differ from them chiefly in size. The successors of the deciduous molars may differ likewise in shape, in which case they have always less complex crowns than their predecessors.

The "bicuspid" in human anatomy, and the corresponding teeth called "premolars" in the lower mammals, illustrate this law.

The Mammalian class might be divided, in regard to the succession of the teeth, into two groups—the *Monophyodonts*,¹ or those that generate but one set of teeth, and the *Diphyodonts*,² or those that generate two sets of teeth. The *Monophyodonts* include the *Cetacea* and the *Bruta* (*Edentata* of Cuvier); all the other orders are *Diphyodonts*.

The teeth of the *Mammalia*, especially of the *Diphyodonts*, have usually so much more definite and complex a form than those of fishes and reptiles, that three parts are recognised in them, viz. the "fang," the "neck," and the "crown." The fang or root (*radix*) is the inserted part; the crown (*corona*) is the exposed part; and the constriction which divides these is called the neck (*cervix*). The term "fang" is properly given only to the implanted part of a tooth of restricted growth, which fang gradually tapers to its extremity; those teeth which grow uninterruptedly have not their exposed part separated by a neck from their implanted part, and this generally maintains to its extremity the same shape and size as the exposed crown.

It is peculiar to the class *Mammalia* to have teeth implanted in sockets by two or more fangs; but this can only happen to teeth of limited growth, and generally characterizes the molars and premolars; perpetually growing teeth require the base to be kept simple and widely excavated for the persistent pulp (figs. 54 and 55). In no mammiferous animal does ankylosis of the tooth with the jaw constitute a normal mode of attachment. Each tooth has its particular socket, to which it firmly adheres by the close co-adaptation of their opposed surfaces, and by the firm adhesion of the alveolar periosteum to the organized cement which invests the fang or fangs of the tooth.

True teeth implanted in sockets are confined, in the *Mammalian* class, to the maxillary, premaxillary, and mandibular or lower maxillary bones, and form a single row in each. They may project only from the premaxillary bones, as in the Narwhal, or only from the lower maxillary bone, as in *Ziphius*; or be apparent only in the lower maxillary bone, as in the Cachalot; or be limited to the superior and inferior maxillaries, and not present in the premaxillaries, as in the true Ruminants and most *Bruta*.

The teeth of the *Mammalia* usually consist of hard unvascular dentine, defended at the crown by an investment of enamel, and everywhere surrounded by a coat of cement. The coronal cement is of extreme tenuity in Man, *Quadruman*, and terrestrial *Carnivora*; it is thicker in the *Herbivora*, especially in the complex grinders of the Elephant, and is thickest in the teeth of the Sloth, *Megatherium*, Dugong, Walrus, and Cachalot. Vertical folds of enamel and cement penetrate the crown of the tooth in the Ruminants, and in most Rodents and Pachyderms, characterizing by their various forms the genera of the last two orders; but these folds never converge from equidistant points of the circumference of the crown towards its centre. The teeth of the quadrupeds of the order *Bruta* (*Edentata*, Cuv.) have no true enamel; this is absent likewise in the molars of the Dugong and the Cachalot. The tusks of the Narwhal, Walrus, *Dinotherium*, Mastodon, and Elephant, consist of modified dentine, which, in the last two great proboscidean animals, is properly called "ivory," and is covered by cement.

The Dolphins and *Armadillos* present little variety in the shape of the teeth in the same animal, and this

² *δύς*, twice; *φύω*, and *οδούς*.

Teeth of
Mammals.

same form is characteristic of most of the Monophyodonts, in which, therefore, the teeth are not divisible into distinct kinds.

In almost all the other Mammalia, particular teeth have special forms for special uses: thus, the front teeth, from being commonly adapted to effect the first coarse division of the food, have been called cutters or *incisors*; and the back teeth, which complete its comminution, grinders or *molars*; large conical teeth, situated behind the incisors, and adapted by being nearer the insertion of the biting muscles, to act with greater force, are called holders, tearers, laniaries, or more commonly *canine* teeth, from being well developed in the dog and other Carnivora, although they are given, likewise, to many vegetable feeders for defence or combat; *e. g.*, Musk-deer. Molar teeth, which are adapted for mastication, have either tuberculate, or transversely rigid, or flat summits, and usually are either surrounded by a ridge of enamel, or are traversed by similar ridges arranged in various patterns. Certain molars in the Dugong, the Mylodon, and the Zeuglodon, are so deeply indented laterally by opposite longitudinal grooves, as to appear, when abraded, to be composed of two cylindrical teeth cemented together, and the transverse section of the crown is bilobed. The teeth of the *Glyptodon* were fluted by two analogous grooves on each side. The large molars of the Capybara and Elephant have the crown cleft into a numerous series of compressed transverse plates, cemented together side by side. The modifications of the crown of the molar teeth are those that are most intimately related to the kind of food of the animal possessing them. Thus, in the purely carnivorous mammals, the molars are simple, trenchant, and play upon each other like scissor-blades. In the mixed feeding species, the working surface of the molars becomes broader and tuberculated; in the insectivorous species it is bristled with sharp points; and in the purely herbivorous kinds, the flat grinding surface of the teeth is complicated by folds and ridges of the enamel entering the substance of the tooth, the most complex forms being presented by the Elephants.

Ornitho-
rhyngchus.

The substances serving for teeth in the anomalous Duck-mole or Platypus of Australia, are of a horny texture, consisting of close-set, vertical hollow tubes, resembling the outer compact tissue of baleen or "whalebone." They are eight in number, four in the upper, and as many in the under jaw. The anterior tooth of the upper jaw (fig. 48, *a*) is extended from behind forwards, but is low, very narrow,

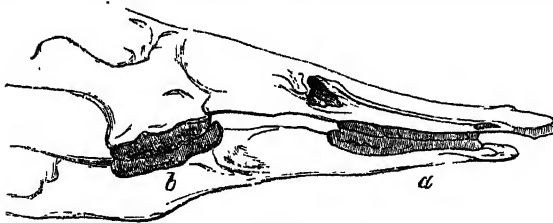

Fig. 48.

Jaws and Teeth of the Platypus, (*Ornithorhynchus paradoxus*).

and four-sided; the broadest side forms the base of attachment, and is slightly concave; the outer and inner facets converge to a serrated edge in the young *Ornithorhynchus*, but becomes worn in the old animal, and forms the fourth side of the tooth. The corresponding tooth in the lower jaw is rather narrower, and retains longer its trenchant edge.

At a distance from the anterior tooth, equal to its own length, is situated the horny molar (*b*), which consists of a flattened plate of an oblong subquadrate figure. A slightly raised margin includes two large concave surfaces, a little elevated above the intervening part of the grinding surface. The corresponding tooth in the lower jaw is somewhat narrower, but of similar form. Each division or tubercle of the molar is separately developed, and they become confluent in the course of growth. According to the analysis of Lassaigne, 99.5 parts of the dental tissue of the *Ornithorhynchus* have the composition of horn; this is hardened by 0.3 parts of phosphate of lime.

Teeth of
Mammals.

The notice of the dental apparatus of the Monotremes ought to include mention of the two short and thick conical processes which project from the forepart of the raised intermolar portion of the tongue, in the *Ornithorhynchus*; which, like the more numerous spines on the corresponding part of the tongue of the *Echidna*, represent, in these low-organized mammals, the lingual teeth of fishes.

The teeth of the *Orycteropus*, or Cape Ant-eater, are of a simple Order form, but peculiar structure; their common number in the mature *Bruta* animal is $7 \frac{1}{2} = 26$ (fig. 49, *A*), and they all belong to the molar series.

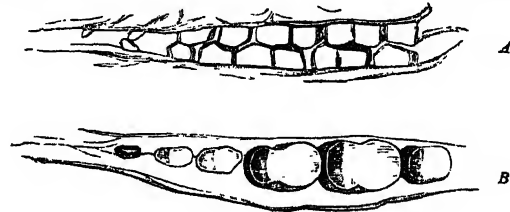

Fig. 49.

Teeth of the Cape Ant-eater, (*Orycteropus*).

The anterior teeth are very small, and are not unfrequently wanting, or are concealed by the gum, especially the first in the upper jaw; the second tooth of the upper jaw is small, compressed, and obtuse; it opposes a similar one in the lower jaw; the third and fourth molars increase in size, have an elliptical transverse section, and a triturating surface of two facets (fig. 49, *B*); the fourth and fifth molars are the largest in the upper jaw, are of equal size, and have a longitudinal depression in their internal and external sides, giving their transverse section a bilobed or hour-glass figure; the seventh molar is smaller and has the same simple figure as the fourth, (fig. 49, *B*). The proportions of these teeth, the depth of their sockets, and their structure, as viewed in longitudinal section with the naked eye, are shown in fig. 50. The teeth are continued solid, and of the

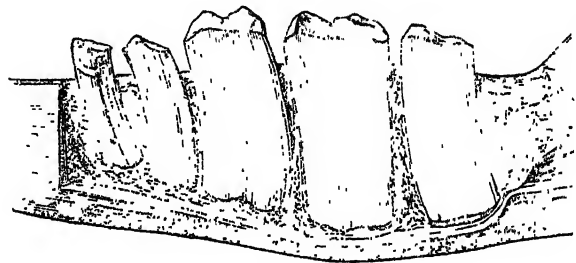

Fig. 50

Section of Lower Jaw and Teeth of the *Orycteropus*. Nat. size.

same dimensions, to the bottom of the socket, and terminate by a truncate and undivided base. If each be viewed as an aggregate of teeth, as partially shown in fig. 15, it will be found that the component denticle has its base excavated by a conical pulp-cavity, as in other animals, and which is persistent, as in the rest of the order *Bruta*. The wide inferior apertures of these pulp-cavities constitute the pores observable on the base of the compound tooth of the *Orycteropus*, and give to that part a close resemblance to the section of a cane. The canals to which these pores lead are the centres of radiation of the calciferous tubes of the denticle, (fig. 15); such denticles are cemented together laterally, slightly decreasing in diameter, and occasionally bifurcating as they approach the grinding surface of the tooth. The substance of the entire tooth thus resembles the teeth of the *Myliobates* and *Chimæroids* among fishes, rather than any true teeth in the Mammalian class, in which it offers a transitional step from the horny substitutes of teeth above described to the true teeth.

The teeth of the *Orycteropus*, when rightly understood, offer, however, no anomaly or exceptional condition in their mode of development. Each denticle is developed according to the same laws, and by as simple a matrix as those larger teeth in other mammals, which consist only of dentine and cement. The dentine is formed by ossification of the capsule; both pulp and capsule continue to be reproduced at the bottom of the alveolus, *pari passu* with the attrition of the exposed crown; and the mode and time of growth being alike in each denticle, the whole compound tooth is maintained throughout the life of the animal. The augmentation in the size of the whole tooth, during the growth of the jaw, is effected by the development of new denticles, and a slight increase of size in the old ones, at the base of the growing tooth, which, in the progress of attrition and growth, becomes its grinding surface.

The teeth of the Armadillo-tribe are harder than those of any Genus other species of the order *Bruta*; but, as in all that order provided *Dasypus* with teeth, they are wholly devoid of enamel. They consist, in

Teeth of Mammals.

both existing and extinct Armadillos, of three distinct substances, of which the unvascular dentine is present in greatest proportion, and forms the main body of the tooth; but it includes a small central axis of vascular dentine, and is surrounded by an extremely thin coating of cement. The teeth are more numerous in the Priodont—the largest of the existing Armadillos—than in any other land mammal; but they are of very small size and simple form, and are all referable to the molar series (fig. 51). They vary

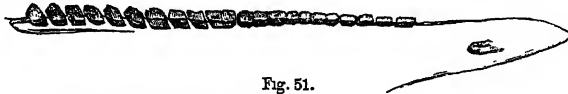

Fig. 51.

Teeth of the Lower Jaw of the Great Armadillo, (*Priodon gigas*).

in number from twenty-four to twenty-six in each upper jaw, and from twenty-two to twenty-four on each side of the lower jaw, amounting to from ninety-four to one hundred in total number. They are compressed laterally, increasing in size, and especially in breadth, as they recede backwards, with oblique or horizontal flat grinding surfaces, and are continued of the same size and form to their implanted extremity, which is excavated by a large conical pulp-cavity. This absence of roots, and the undivided hollow base indicative of the constant growth of the tooth, are common not only to the teeth of the Armadillos, but to those of all the known species of the order *Bruta*.

In the Priodont the teeth, though so unusually numerous, are many of them separated by slight intervals; those of the lower jaw oppose their outer sides to the inner sides of the upper teeth when the mouth is shut.

The Armadillos of the sub-genus *Euphractus*, Wagler, to which the term *Dasypus* is restricted by F. Cuvier, are distinguished by having the anterior tooth (fig. 52, *i*), which is shaped like the succeed-

Fig. 52.

Jaw teeth of the weasel-headed Armadillo, (*Dasypus 6-cinctus*).

ing molar, implanted in the premaxillary bone. The two anterior teeth of the lower jaw being in advance of the premaxillary tooth, are, with it, arbitrarily held to be incisors; they are compressed, but are terminated by obtuse crowns. The rest of the series, from which the incisors are not separated by any remarkable interval, gradually increase in size to the penultimate molar; they have the same alternate position and obliquely-worn grinding surfaces as in the *Tatusia*.

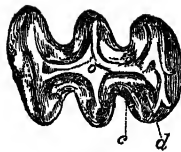

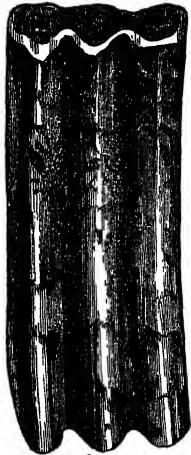

Fig. 53.

Tooth of great extinct Armadillo, (*Glyptodon clavipes*).

Some species of the extinct loricate genus, *Glyptodon*, surpassed the Rhinoceros in size, and the dentition of the genus was more complicated, and more adapted to a vegetable diet, than that of the small existing Armadillos. The total number of teeth in the *Glyptodon* has not yet been determined. A fragment of the anterior part of the lower jaw shows that the teeth extend close to the symphysis, and therefore indicates their presence in the premaxillary bones above.

The single tooth (fig. 53), on which the generic character of the *Glyptodon* was founded,¹ is long, rootless as in the existing Armadillos, but compressed laterally, and divided by two deep angular, longitudinal, and opposite grooves on each side, into three plates, which give the grinding surface the form of as many rhomboidal lobes. In the *Glyptodon* the osteo-dentine (fig. 53, *o*) occupies a larger proportion of the centre of the tooth than in the small Armadillos; it is harder than the dentine (*d*) or cement (*c*), and rises upon the grinding surface, in the form of a ridge extending along the middle of the long axis of that surface, and in three shorter ridges at right angles to the preceding, at the middle of each of the three rhomboidal divisions of the tooth.

Of the leaf-eating species of the order *Bruta*, very few, and these

the most diminutive of the tribe, now exist. They are called Sloths, or Tardigrades, from their inability to move otherwise than slowly and with difficulty on the ground; but they are excellent climbers, for which their organization especially befits them.

The following are the common and constant characters of the dentition of the phyllophagous *Bruta*, both recent and extinct:—Teeth implanted in the maxillary and mandibular bones, few in number, not exceeding $\frac{1}{2}$; composed of a large central axis of vaso-dentine, with a thin investment of hard dentine, and a thick outer coating of cement. To these, of course, may be added the dental characters common to the order *Bruta*, viz., uninterrupted growth of the teeth, and their concomitant implantation by a simple, deeply-excavated base, not separated by a cervix from the exposed summit or crown.

The dental formula of the genus *Bradypus* is— $i \frac{0}{0}$; $c \frac{0}{0}$; $m \frac{2}{2}$ —18. Dr Brandt² has described and figured the skull of a young *Ai*, in which a very small tooth preceded the compressed one on each side of the lower jaw, rendering the number of teeth equal to that in the upper jaw. In the two-toed sloth (*Cholepus didactylus*, Illig.) the teeth (fig. 54) offer a greater inequality of size than has yet been observed in any other genus of *Bruta*; the first of each series, *a*, in both jaws, which in the rest of the order is the smallest, here so much exceeds the others as, with its peculiar form, to have received the name of a canine. This tooth is separated by a marked interval from the other teeth, especially in the upper jaw, so that those above play upon the anterior part of those below, contrary to the relative position and mutual action of the true canine teeth in the *Quadrumania* and *Carnivora*.

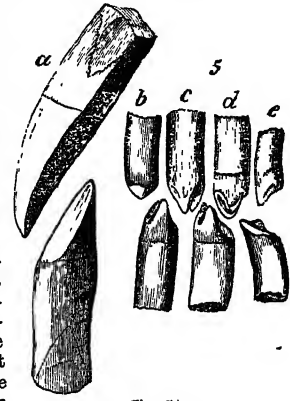

Fig. 54.

Teeth of the two-toed Sloth (*Cholepus didactylus*).

They are of a triedral form, with the margins of the oblique abraded surface leading to the point, trenchant. The second tooth of the upper jaw (*b*) is the smallest of the series. The third (*c*) and fourth (*d*) molars are a little larger, and have two abraded surfaces which converge to the median ridge. The fifth molar (*e*) is the smallest, and has an oblique grinding surface. In each tooth the ridge is formed by the hard dentine, and is interrupted in the middle by an excavation of the soft dentine. The second, third, and fourth teeth of the lower jaw correspond in size and shape with the third and fourth above; and like the small upper molars, are separated by short intervals; the last is the smallest and most curved.

The teeth of the Sloths consist of a central axis of vaso-dentine (fig. 9, *v*), occupying rather more than half the thickness of the tooth, which is inclosed by a wall of unvascular dentine (*d*), and this by one of cement (*c*) of less thickness than the layer of hard dentine.

Megatherium.

undulating course, having regular interspaces equal to one diameter and a half of their own area, generally anastomosing in pairs by a loop (*l*), the convexity of which is turned towards the origin of

Fig. 57.

Highly magnified Section of the Dental
Tissues, Megatherium.

ample of a course of nutriment from the dentine to the cement, and reciprocally. In the structure which the fossil teeth of the Megatherium and its extinct congeners clearly demonstrate, we have striking evidence of their rich organization, and that they were once pervaded by vital activity. All the constituents of the blood freely circulated through the vascular dentine and the cement, and the vessels of each substance, intercommunicated by a few canals, continued across the hard or unvascular dentine.

With respect to those minuter tubes, the more important as being more immediately engaged in nutrition, which pervade every part of the tooth, characterizing by their difference of length and course the

Each molar tooth of the Megatherium is excavated by an unusually extensive conical pulp-cavity (*p*), from the apex of which a fissure is continued to the middle depression of the grinding surface of the tooth (*v*). The central axis of vaso-dentine (*v*) is surrounded by a thin layer of hard or unvascular dentine (*d*), and this is coated by the cement (*c*), which is of great thickness on the anterior and posterior surfaces, but is thin where it covers the outer and inner sides of the tooth. The vaso-dentine (fig. 57, *v*) is traversed throughout by medullary canals, measuring $\frac{1}{1000}$ of an inch in diameter, which are continued from the pulp-cavity, and proceed, at an angle of 50° , to the plane of the hard dentine, parallel to each other, with a slightly

forming a continuous reflected canal. The loops are situated near, and for the most part close to, the hard dentine (*d*). In a few places one of the medullary canals may be observed to extend across that tissue. The cement (fig. 57, *c*) is characterized by the size, number, and regularity of the vascular or medullary canals (*m*) which traverse it. They present the diameter of $\frac{1}{1000}$ of an inch, are separated by intervals equal to from four to six of their own diameters. Commencing at the outer surface of the cement, they traverse it in a direction slightly inclined from the transverse axis towards the crown of the tooth, running parallel to each other; they divide a few times dichotomously in their course; and finally anastomose in loops, the convexity of which is directed towards, and in most cases is in close contiguity with, the hard dentine (*d*). Fine tubules are sent off, generally at right angles from the medullary canals, which quickly divide and subdivide, form anastomosing reticulations, and communicate freely with the similar tubes that radiate from the calciferous cells of the intervening tissue (*r*).

The tooth of the Megatherium thus offers an unequivocal example of a course of nutriment from the dentine to the cement, and reciprocally. In the structure which the fossil teeth of the Megatherium and its extinct congeners clearly demonstrate, we have striking evidence of their rich organization, and that they were once pervaded by vital activity. All the constituents of the blood freely circulated through the vascular dentine and the cement, and the vessels of each substance, intercommunicated by a few canals, continued across the hard or unvascular dentine.

With respect to those minuter tubes, the more important as being more immediately engaged in nutrition, which pervade every part of the tooth, characterizing by their difference of length and course the

three constituent substances, they form one continuous and freely intercommunicating system of strengthening and reparative vessels, by which the plasma of the blood was distributed throughout the entire tooth, for its nutrition and maintenance in a healthy state.

The grinding surface of the close-set molars of the Megatherium differs, on account of the greater thickness of the cement on their anterior and posterior surfaces, from those of all the smaller Megatherioids, in presenting two transverse ridges (fig. 56, *d*), one of the sloping sides of each ridge being formed by the cement (fig. 55, *c*), the other by the vascular dentine (fig. 55, *v*), whilst the unvascular dentine (*d*), as the hardest constituent, forms the summit of the ridge like the plate of enamel between the dentine and cement in the Elephant's grinder. The great length of the teeth, and concomitant depth of the jaws, the close-set series of the teeth, and the narrow palate, are also strong features of resemblance between the Megatherium and Elephant in their dental and maxillary organization. In both these gigantic phyllophagous quadrupeds, provision has likewise been made for the maintenance of the grinding machinery in an effective state throughout their prolonged existence; but the fertility of the creative resources is well displayed by the different modes in which this provision has been effected; in the Elephant, it is by the formation of new teeth to supply the place of the old when worn out; in the Megatherium, by the constant repair of the teeth in use, to the base of which new matter is added in proportion as the old is worn away from the crown. Thus, the extinct Megatherioids had both the same structure and mode of growth and renovation of their teeth as are manifested in the present day by the diminutive Sloths.

Those cetaceous Mammals which are properly called "Whales" have no teeth, but horny substitutes in the form of plates, terminating or fringed by bristles. Of these plates, called "Baleen" and "Whalebone," the largest, which are of an equilateral triangular form, are arranged in a single longitudinal series on each side of the upper jaw, situated pretty close to each other, depending vertically from the maxillary bones, with their flat surfaces looking backwards and forwards, and their unattached margins outwards and inwards, the direction of their interspaces being nearly transverse to the axis of the skull. The smaller subsidiary plates are arranged in oblique series internal to the marginal ones. Thus, if the upper jaw of one side of the skull of a Whale were bisected transversely, the flat surface of a series of the baleen-plates would be exposed, as in fig. 58, in which *a* is the superior maxillary bone, *b* the ligamentous gum giving attachment to *a*, the horny base and body of the chief baleen-plate, which terminates in *d*, the fringe of bristles; *e* marks the smaller baleen-plates.

The base of each plate is hollow, and is fixed upon a pulp developed from a vascular gum, which is attached to a broad and shallow depression occupying the whole of the palatal surface of the maxillary and of the anterior part of the palatine bones, the Whale being thus, like Echidna, an example of a mammalian animal, which may be said to have palatal teeth.

The base of each plate is unequally imbedded in a compact sub-elastic substance (*b*), which is so much deeper on the outer than on the inner side, as, in the new-born whale, to include more than one half of the outer margin of the baleen-plate. This margin is shown at *c* (fig. 58), and is continued downwards in a line dropped nearly vertically from the outer border of the jaws. The inner margin of each plate (*d*) slopes obliquely outwards from the base to the extremity of the preceding margin; the smaller plates decrease in length to the middle line of the palate, so that the form of the baleen-clad roof of the mouth is that of a transverse arch or vault, against which the convex dorsum of the thick and large tongue is applied when the mouth is closed. Each plate sends off from its inner and oblique margin the fringe of moderately stiff but flexible hairs, which project into the mouth.

The direction of the plates is not quite transverse at every part of

Teeth of
Mammals.

Whales.

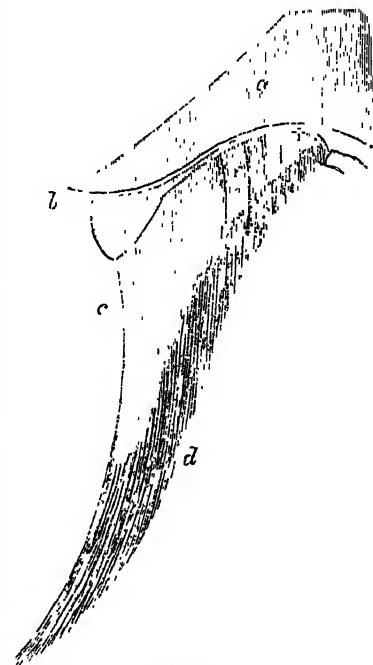

Fig. 58.

Section of Upper Jaw, with Baleen-plates, of a
Whale (*Balainoptera*).

Teeth of Mammals.

the series; the inner border is turned rather forwards in the anterior, and obliquely backwards in the posterior plates; and the inner margin at the basal part of the posterior plates is slightly curved towards the back part of the mouth, to which the bristly terminations of these parts of such plates are directed, thus presenting an additional obstacle to the escape of the small marine animals,¹ for the prehension and detention of which this singular modification of the dental system is especially adapted. The baleen-pulp is situated in a cavity at the base of the plate, like the pulp of a true tooth; whilst the external cementing material maintains, both with respect to this pulp and to the portion of the baleen-plate which it develops, the same relations as the dental capsule bears to the tooth. According to these analogies, it must follow, that only the central fibrous or tubular portion of the baleen-plate is formed, like the dentine, by the basal pulp, and that the base of the plate is not only fixed in its place by the cementing substance or capsule, but must also receive an accession of horny material from it, as Hunter first indicated; this material answers to the cement of true teeth.

Mr Scoresby, who in his account of the *Balæna mysticetus*, notices only the large marginal plates, states that they are about two hundred in number on each side; the largest are from ten to fourteen feet, very rarely fifteen feet, in length, and about a foot in breadth at their base; these plates are overlapped and concealed by the under lip when the mouth is shut.

In the *Balænoptera* or fin-backed whales (fig. 58), the baleen-processes (e), internal to the marginal plates, are fewer and smaller than in the *Balæna*, the marginal plates (c) are more numerous, exceeding three hundred on each side; they are broader in proportion to their length, and much smaller in proportion to the entire animal; they are also more bent in the direction transverse to their long axis. As in the true whales, each plate of baleen consists of a central, coarse, fibrous substance, and an exterior, compact, fibrous layer, beyond which the central part projects in the form of the fringe of bristles.

A thin transverse section of baleen, viewed with a low magnifying power, demonstrates that the coarse fibres, as they seem to the naked eye, which form the central substance, are hollow tubes with concentric laminated walls. When a high magnifying power is applied to such a section, the concentric lines are shown not to be uniform, but interrupted here and there by minute elliptical dilata-tions, which are commonly more opaque than the surrounding substance, and which, like the radiated cells of true bone, are probably remains of the primitive cells of the formative substance; similar long elliptical opaque bodies or cells are dispersed irregularly through the straight parallel fibres of the dense outer laminæ of the baleen-plate.

The chemical basis of baleen, according to Brandt, is albumen hardened by a small proportion of phosphate of lime.

The singular armature of the palate and lower jaw, in the *Rytina*, or Arctic Dugong, likewise falls within the present category. According to Steller,² this marine animal has no true teeth, but only two large whitish dental masses, one adhering to the palate, the other to the opposed part of the lower jaw. They are not im- planted by gomphosis, but adhere by numerous pores to correspond- ing papillæ of the membrane covering the palate and lower jaw; besides which, the palatal tooth is fixed at the sides of its anterior part to furrows in the lining membrane of the thick lip. The free surface of the dental mass is sculptured by undulating grooves and risings, adapted to corresponding inequalities in the opposite mass.

Dr Brandt has shown by later and more minute examination of the problematical teeth of the *Rytina*, deposited by Steller in the Petersburg collection, that their texture is horny, consisting of minute hollow fibres, placed vertically to the plane of the grinding surface of the tooth, but of unusual density. Thus the dentition of the *Rytina* closely resembles that of the *Ornithorhynchus* in both the texture and implantation of the teeth, which will probably be found to contain a similar or greater proportion of osseous matter. M. F. Cuvier has suggested that the above-described plates may be analogous in position, as in texture, to the horny covering of the opposed surfaces of the deflected portions of the upper and lower jaws in the Dugong.

The true Whales (*Balænidæ*), before they acquire their peculiar array of baleen-plates, manifest in their fetal age a transitory condition of a true dental system, which, though abortive and functionless, beautifully typifies that which is normal and persistent in the majority of the order.

In an open groove (fig. 59, a) which extends along the alveolar border of both the upper and the lower jaws, there is a series of

minute, conical, acute, or obtuse denticles, (fig. 59, 1-7), with hollow bases inclosing the uncalcified remains of a vascular pulp. In the fetus of a *Balænoptera*, the jaws of which were about four inches in length, the unclosed alveolar groove of the upper jaw contained

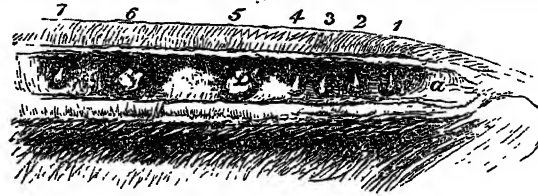

Fig. 59.

Extremity of Lower Jaw of a Fœtal Whale, with the Denticles. Nat. size.

twenty-eight such denticles, that of the lower jaw forty-two. The anterior denticles in both jaws were the smallest; but they increase in size more gradually, and maintain a greater regularity of form in the lower jaw, where they are also most numerous, and in which the typical dentition of the carnivorous cetaceans manifests its plenary development in the great Cachalot.

Fig. 60 exhibits three of the transitory teeth of a fœtal Whale: one is simple, with the fang contracted to a point by the diminution and cessation of growth; the next tooth shows two fangs; and the third, more plainly, the origin of its double character to two contiguous and partly confluent tooth-germs.

Fig. 60.

These small teeth and their matrices disappear before birth; yet the fœtal Whale comparatively long retains and palpably exemplifies the earliest stage of dental development in the higher Mammals, viz., the open fissure which in these is so rapidly closed, especially in the human subject. But beyond this stage, the true dentition of the *Balænidæ* is not destined to proceed, and they thus manifest, agreeably with the general laws of unity of organization, their closest relations to the typical characters of their order at the early periods of development—divesting themselves of part of the more general type, in order to assume their special and distinctive characters, as they advance towards maturity.

The great Bottle-nose or bi-dent Whale offers a transitional grade between the true Whales and the typical *Delphinidæ*. The palate is said to be beset with small, unequal, pointed, callous protuberances, which Cuvier conjectures to be rudimental baleen-plates. The fœtal denticles do not all perish, but two or three of the anterior pairs acquire a large size as compared with their transitory representatives in the *Balænidæ*—and one of these pairs is long retained in the lower jaw, though functionless, and hidden by the gum.

These teeth are figured, as seen, when the gum has been removed, at the extremity of the lower jaw of the *Hyperoodon*, in cut 61, b. They are conical, slightly curved, with an unusually sharp and slender apex, tipped by enamel. Though loose in their sockets, they project so little from them, and have such wide bases, that they are retained *in situ*, and do not fall out in the dried jaw; two smaller cavities (fig. 61, a) in front, and the remains of a larger socket in the alveolar groove, behind the retained teeth, attest the former presence of other teeth. Mr. Thompson of Belfast³ has figured the lower jaw of a *Hyperoodon* with two small teeth on each side, near the symphysis; they were concealed by the gum, and so hidden in the sockets, as not to be visible in a side view of the jaw. The animal was a male, and twenty-three feet long; the first tooth was seven and a half lines from the end of the jaw; the second tooth was one and a half inch distant from the first.

In the Narwhal (*Monodon monoceros*), two of the primitive dental germs at the forepart of the upper jaw proceed in their development to a greater extent than do those in the lower jaw of the *Hyperoodon*; but every other trace of teeth is soon lost. The two persistent matrices rapidly elongate, but in the retrograde direction, forming a long fang rather than a crown; each tooth sinks into a horizontal alveolus of the premaxillary bone, or, rather, at the junction of the

Teeth of Mammals.

premaxillary with the maxillary, and soon, by the forward growth of these bones, becomes wholly inclosed, like the germs of the teeth of the higher Mammalia at their second stage of development. In the female Narwhal, the pulp is here exhausted, the cavity of the tooth is obliterated by its ossification, further development ceases, and the two teeth remained concealed, as abortive germs, in the substance of the jaws for the rest of life, so that in the skeleton a section of the

skull must be made in order to display them, as in fig. 61, B. In the male Narwhal, (fig. 61, A) the matrix of the tooth in the left premaxillary bone continues to enlarge; fresh pulp material is progressively added, which by its calcification elongates the base, protrudes the apex from the socket, and the tusk continues to grow until it acquires the length of nine or ten feet, with a basal diameter of four inches. This is that famous "horn" which figures on the forehead

Teeth of Mammals.

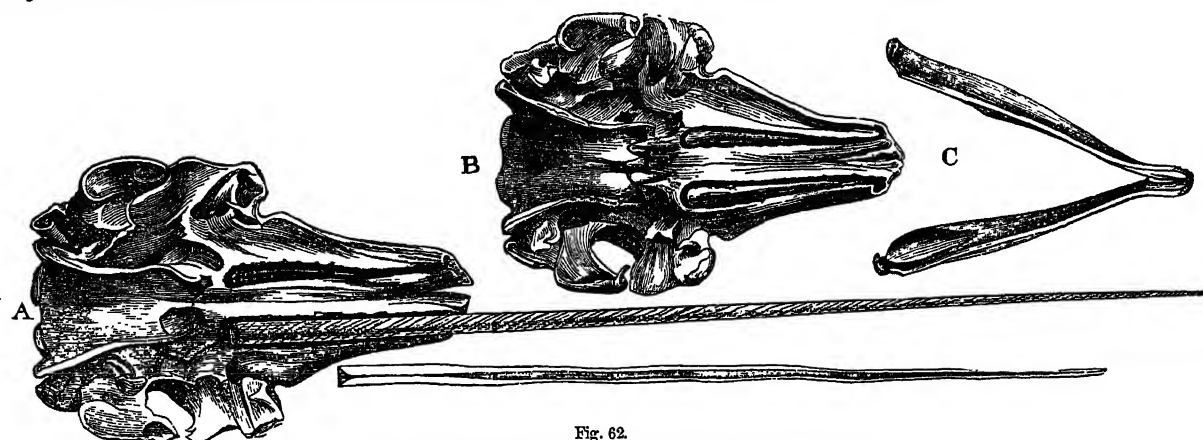

Fig. 62.

Base of Skulls of Male and Female Narwhal, with the Tusks and Lower Jaw.

of the heraldic unicorn, and so long excited the curiosity and conjectures of the older naturalists, until Olaus Wormius made an end of the speculative and fabulous "monocerologies," by the discovery of the true nature of their subject; whilst Anderson¹ in the year 1736, took advantage of the accident of the stranding of a Narwhal at the mouth of the Elbe, to communicate to the zoological world an accurate figure of the animal which bore the supposed single horn. Linnæus has embalmed the old idea of this weapon in the binomial *Monodon monoceros*, under which the Narwhal is entered in the *Systema Naturæ*.

The exterior of the long tusk is marked by spiral ridges, which wind from within forwards, upwards, and to the left. About fourteen inches is implanted in the socket; it tapers gradually from the base to the apex. The pulp-cavity, as shown in the longitudinal section of the tusk, given in fig. 62, is continued nearly to the extreme point, but is of variable width; at the base it forms a short and wide cone; it is then continued forwards, as a narrow canal, along the centre of the implanted part of the tooth, beyond which the cavity again expands to a width equalling half the diameter of the tooth; and finally, but gradually, contracts to a linear fissure near the apex.

Thus, the most solid and weighty part of the tooth is that which is implanted in the jaw, and nearest the centre of support, whilst the long projecting part is kept as light as might be compatible with the uses of the tusk as a weapon of attack and defence. The portion of pulp, in which the process of the calcification has been arrested, receives its vessels and nerves by the fissure continued from the basal expansion of the pulp-cavity.

In a few instances, both tusks have been seen to project from the jaw. In the cranium of such a Narwhal, figured by Albers, the right tusk projects only six inches from the socket, is proportionally slender, and is smooth.

With regard to the conjectured ulterior use of the concealed tusk (fig. 62, A), in the male, as a potential substitute, in the event of the loss of the large tusk, a conjecture more than once repeated by writers since first proposed by Reisel, the solidity of the concealed tusk, and its distorted and generally-closed base, evince that the term of its growth has expired.

In the *Delphinus griseus*, the dentition of the upper jaw is transitory, as in *Hyperoodon*, but at least six pairs of teeth rise above the gum, and acquire a full development at the forepart of the lower jaw. The crowns of these teeth soon become obtuse, and even their duration is limited, for the specimen described by M. F. Cuvier² had but two teeth on each side of the lower jaw. A Dolphin, perhaps an aged individual of this species, has been lately described with the dentition reduced to two teeth in the lower jaw.

Physeter.

The outward and visible dentition of the great Sperm-whale or Cachalot (*Physeter macrocephalus*) is confined to the lower jaw. The series consists in each ramus of about twenty-seven sub-incurved, conical, or ovoid teeth, according to their state of development and usage; the smallest teeth are at the two extremes of the series. In the young Cachalot they are conical and pointed; usage soon renders them obtuse, whilst progressive growth expands and elongates the base into a fang, which then contracts, and is finally solidified and terminated obtusely. The teeth are separated by

intervals as broad as themselves. In respect of their mode of implantation in the jaw, they offer in the Cachalot a condition intermediate between that of the teeth of the extinct cetaceous-like *Ichthyosaurus*, and of those of the piscivorous *Delphinus*. They are lodged in a wide and moderately-deep groove, imperfectly divided into sockets, the septa of which reach only about half-way from the bottom of the groove. These sockets are both too wide and too shallow to retain the teeth independently of the soft parts, so that it commonly happens, when the dense semi-ligamentous gum dries upon the bone, and is stripped off in that state, that it brings away with it the whole series of the teeth like a row of wedges half driven through a strip of board. A firmer implantation would seem unnecessary for teeth which have no opponents to strike against, but which enter depressions in the opposite gum when the mouth is closed. That gum, however, conceals a few persistent specimens of the primitive foetal series of teeth; these (of which one is shown at the upper part of fig. 63) are always much smaller and more curved than the functional teeth of the lower jaw, of which a section is given in the same cut.

There is a well-marked sexual distinction in the size of the jaws of the *Physeter macrocephalus*, those of the mature female being relatively shorter by full one-third than in the male. There are usually twenty-three teeth in each ramus of the lower jaw of a full-sized female Cachalot.

The first-formed extremity of the tooth in the young Cachalot is tipped with enamel; when the summit of the crown has been abraded, the tooth consists of a hollow cone of dentine (fig. 63, d), coated by cement (c), and more or less filled up by the ossified pulp (o). Irregular masses of this fourth substance have been found loose in the pulp-cavity of large teeth. The external cement is thickest at the junction of the crown and base, which are not divided by a neck.

The permanent or mature dentition of the Beluga (*Delphinus leucas*, Pall.), though scanty, is more normal than in the *Physeter*, nine functional teeth being retained on each side of the upper jaw, and eight in each ramus of the lower jaw. They present the form of straight subcompressed obtuse cones. The *Delphinus globiceps*,

Teeth of
Mammals.

which has $\frac{1}{2}:\frac{1}{2}=52$, strong, conical, and pointed teeth in the vigour of its age, begins soon after to lose them, and in old individuals none remain in the upper jaw, and not more than eight or ten are preserved in the lower jaw; those at the anterior part of the jaws last longest, and their summits are received in cavities in the upper jaw, or the gum covering it, when the mouth is shut.

The most formidable dentition is that of the predaceous Grampus (*Phocaena orca*), whose laniariform teeth are as large in proportion to the length of the jaws as in the crocodile; they are in number $\frac{1}{2}:\frac{1}{2}=50$; all fixed in deep and distinct sockets, separated by interspaces which admit of the close interlocking of the upper and lower teeth when the mouth is closed; the longest and largest teeth are at the middle of the series, and they gradually decrease in size as they approach the ends, especially the posterior one; the shortness of the anterior teeth is in great part due to the wearing down of the sharp summits, which are best preserved in the small posterior teeth; the position of the bruising and piercing teeth being the reverse of what commonly obtains.

The tooth continues to expand below the enamelled crown to the middle of the fang, which is three times the length, or more, of the crown; it then gradually diminishes to a truncated base, more or less excavated, according to the age of the tooth. The expanded ventricose fang is subcompressed and flattened at the sides. A worn tooth of an old Grampus much resembles the canine of the *Ursus spelæus*; but the long ventricose fang of that is flattened only on one side, is convex at the other, and the pulp cavity is obliterated long ere the crown is worn down; the base of the enamel is more evenly circular, less oblique from the convex to the concave side of the crown; the fang in the Grampus is marked by many wavy transverse lines of growth.

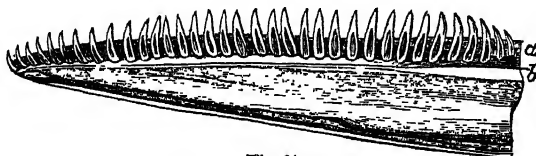

In the common Dolphin the number of teeth amount to 190, arranged in equal numbers above and below, and there is a pair of teeth in the premaxillaries which are toothless in the other *Cetacea*. They have slender, sharp, conical, slightly incurved crowns, and diminish in size to the two extremes of the dental series; the acute apices are longer preserved than in the foregoing species.

The teeth of the common Porpoise (*Phocaena vulgaris*) are arranged in equal number on each side of both upper and lower jaws, and are from 80 to 92 in number; the crown is slightly expanded and compressed, and the fully-formed fang is recurved and enlarged at its extremity.

The Gangetic Dolphin (*Platanista gangetica*) differs from the rest of the *Delphinidae* scarcely less in the form of its teeth than in that of the jaws. Both the upper and lower maxillary bones are much elongated and compressed; the symphysis of the lower jaw is co-extensive with the long dental series, and the teeth rise so close to it, that those of one side touch the others by their bases, except at the posterior part of the jaw. The lateral series of teeth are similarly approximated in the upper jaw at the median line of union, which line is compelled, by the alternate position of the teeth, to take a wavy course.

There are thirty teeth on each side of the upper jaw, and thirty-two on each side of the lower jaw. In the young animal they are all slender, compressed, straight, and sharp pointed, the anterior being longer than the posterior ones, and recurved. Contrary to the rule in ordinary Dolphins, the anterior teeth retain their prehensile structure, while the posterior ones soon have their summits worn down to their broad bases.

The most remarkable change that occurs in the progress of growth is the antero-posterior expansion, as well as elongation of the implanted base of the tooth, which likewise has its outer surface augmented by longitudinal folds or indentations, analogous to, but weaker than, those in the base of the teeth of the Sauroid fishes. Sometimes the posterior tooth of the *Platanista* has the base divided into two short fangs—the sole example of such a structure which I have met with in the existing carnivorous *Cetacea*.

[Fig. 64.]
Section of Jaw and Teeth of a Dolphin (*Delphinus delphis*).

Develop-
ment.

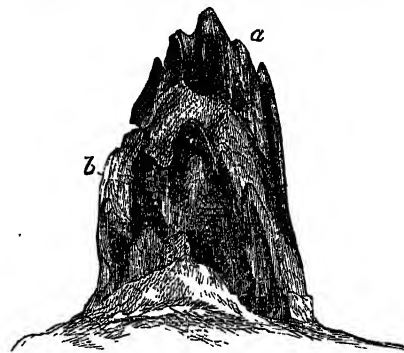

The primitive seat of the development of the tooth-matrix in the vascular membrane or gum (fig. 64, *a*) lining an open groove on the alveolar border of the maxillary bones (*b*), is maintained much longer in the *Cetacea* than in the highest organized *Mammalia*; a greater proportion of the tooth is also developed before the matrix sinks into, or is surrounded by a bony alveolus; and, with the exception of the rudimental tusks in the Narwhal, is

at no period entirely enclosed in a bony cell; in which respect the *Cetacea* offer an interesting analogy to true fishes.

The *Cetacea* permanently represent that early embryonic stage when no cervical constriction divides the large head from the trunk, and when the rudimental limbs offer no outward marks of joints or digits; they likewise retain a preponderating proportion of brain, and manifest for a long period, and on a magnified scale, the first stages in the development of teeth.

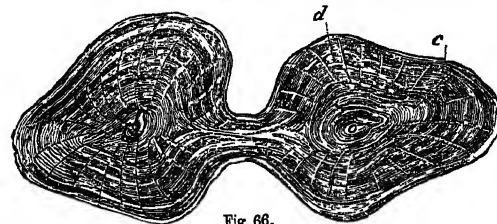

When, by the increasing depth of the jaw, and the reciprocal elongation of the tooth, its base or fang becomes supported by bone (fig. 64, *b*), a longer time than usual elapses before the alveolus is completed by the development of transverse partitions between the outer and inner walls of the open groove; and in the meanwhile the teeth are lodged, like those of the *Ichthyosauri*, in a common and continuous bony channel. In the *Delphinidae* the teeth are successively developed from before backwards, and pass through all their stages of growth in that order of position—the anterior ones having their fangs and alveoli completed, whilst the posterior teeth are lodged in a common groove, or may be supported at the back part of the series by the gum only, as at *a*. When the formation of the entire series of teeth approaches its completion, the Dolphin resembles the Alligator in having the anterior teeth lodged in sockets, and the posterior teeth in an alveolar groove. In the Cachalot the large middle teeth of the series are the last to have the fang solidified. The conversion of the last remnant of the pulp produces the irregular bone-like deposit in the centre of the tooth, and closes up the lower aperture—one or two minute canals for the nutrient vessels being usually left. The mass of this fourth central substance is greatest in the Cachalot (fig. 63, *c*), in which the process sometimes commences at an independent centre, and proceeds centrifugally, as in ordinary ossification, giving rise to the detached stalactitic masses occasionally found loose in the unclosed pulp-cavity of large teeth.

The remains of a gigantic animal discovered in a tertiary formation in the State of Louisiana, and originally interpreted to belong to the class of reptiles with the name of *Basilosaurus*,¹ having presented, in both portions of upper and lower jaws, teeth implanted by a double fang in deep sockets, the writer demonstrated from this character, and the microscopic structure of the teeth, both the mammalian nature and cetaceous affinities of the species, and proposed for it the name of *Zeuglodon*, or yoke-tooth.² The crowns of the large posterior teeth are sub-compressed and conical, with an obtuse apex. The upper part of the crown has its anterior and posterior margins strongly serrated (fig. 65). The crown is contracted from

dinal grooves which produce this form, become deeper as the crown approaches the socket, and at length meet and divide the root of the tooth into two separate fangs. The anterior teeth have a single root, and are somewhat smaller than the posterior ones; the crown is sharp-pointed, conical, slightly recurved and laterally compressed, the transverse section of the base forming an ellipse.

Teeth of Mammals.

The teeth of a species of this genus were figured by SAÏLLA in his work *De Corporibus Marinis*, 4^o, 1747, tab. xii. fig. 1. They have been ascribed, since the above-cited memoir on *Zeuglodon* appeared, by Mr. Grateloup, to a genus called *Squalodon*, and by Dr. Gibbs to a genus called *Dorudon*. The mode of completion of the teeth in this extinct Cetacean is different from, and conforms to, a higher type than that of any of the existing carnivorous genera of the order. It is evident that the pulp which, from the form and structure of the crown, was originally simple, becomes afterwards divided into two parts, and that its calcification then proceeds towards two distinct centres, which are each separately surrounded by concentric stræ of growth. The *cavitas pulpi*, which is very small in the crown of the tooth, becomes contracted as the fangs descend, and is almost obliterated near their extremities.

The summits of the crown of the teeth of the *Zeuglodon* were sheathed with enamel. Their base exhibits an investment of a thin layer of cement, which augments in thickness where it surrounds the fangs.

Dr. CARUS¹ figures a fragment of the under jaw of the *Zeuglodon* (see fig. 65), in which a worn-out deciduous molar appears to be displaced and succeeded vertically by a premolar; this would imply an affinity to the *Sirenia*. In the *Sirenia*, whose dentition will next be described, the two-fanged structure is fully established in the Manatee, whilst the Dugong presents a near resemblance to the *Zeuglodon* in the composition and the intimate structure of the molar teeth. The vertebrae of the *Zeuglodon* resemble those of the carnivorous Cetacea. The size of the extinct animal is estimated at near seventy feet; it accordingly affords a very interesting addition to the history of the dental system in the Cetaceous order, and makes the typical group approach by another step nearer to the Dugongs and Manatees, which are more essentially related to the Pachyderms.

Two marks of inferiority in the dental system of the carnivorous Cetacea, which they have in common with many of the order *Bruta*, viz.—uniformity of shape in the whole series of teeth, and no succession and displacement by a second or permanent set,—disappear when we commence the examination of the dentition of those apodal Pachyderms, which have been called by Cuvier the Herbivorous Cetacea.

In the Dugong (*Halicore*), for example, we find incisors distinguished by their configuration as well as position from the molars, and the incisive tusk is deciduous, displaced vertically, and succeeded by a permanent tusk; both these characters are shown in fig. 67. Of the incisors of the Dugong, only the superior ones project

opposite ends to their tegumentary gum, which presents no outward indication of their presence. Not more than twenty-four molar teeth are developed in the Australian Dugong (*Halicore Australis*), or more than twenty molar teeth in the Malayan Dugong, viz.—in the latter, five on each side of both upper and lower jaws (fig. 67, 1-5), but these are never simultaneously in use, the first being shed before the last has cut the gum.

The period when the molar series can be viewed in its most complete state in the Dugong is that represented in fig. 67. The molar teeth increase very regularly in size; the fang of the first (1) and of the second (2) is soon completed and solidified; that of the third (3) is more elongated, and retains its basal cavity longer, but it becomes at length contracted to a point, solidified, partially absorbed, and the tooth is then shed; the crown presents a regular oval shape in transverse section. The fourth molar, when fully formed, resembles a slightly bent cylinder with a nearly smooth outer surface; the crown is flat, or slightly depressed at the centre. The opposite extremity of the tooth is excavated by a regular conical cavity, lodging the remains of the pulp. With age, however, the fang contracts, takes on an irregularly fluted and tuberculate surface, and is at last closed at its extremity. The matrix of the last molar tooth (5) expands as the crown is forming, and manifests a tendency to divide into two fangs; but having acquired the size and form exhibited in fig. 67, b, in transverse section, the pulp is maintained in a wide basal pulp-cavity, to supply the waste of the crown according to that pattern.

The molar teeth of the Dugong consist of a large body of dentine (fig. 8, d), a small central part of osteo-dentine, and a thick external investment of cement (c). The communications between the tubes of the cement and those of the dentine are clearly discernible in several parts of the circumference of the latter substance, and the whole system of tubes adapted to circulate the plasma of the blood through the solid tissues of the tooth is, perhaps, in no existing mammal better seen than in the molar of the Dugong. The small portion of osteo-dentine in the centre of the tooth is permeated by a few vascular canals, which are derived from the remains of the pulp. In the female Dugong the whole of the smaller extremity of the tusk is surrounded by a thin coat of true enamel, which is covered by a thinner stratum of cement. In the male's tusk the enamel, though it may originally have capped the extremity, as in the female's, yet, in the body of the tusk, it is laid only upon the anterior convex, and on the lateral surfaces, but not upon the posterior concave side of the tusk; which is thickly coated with cement.

This side, accordingly, is worn away obliquely when the tusk comes into use, whilst the enamel maintains a sharp chisel-like edge upon the anterior part of the protruded end of the tusk.

The presence of abortive teeth concealed in the sockets of the deflected part of the lower jaw of the Dugong (fig. 67, a, i d) offers an interesting analogy with the rudimental dentition of the upper jaw in the Cachalot, and of both jaws in the fœtal Whales. The arrested growth and concealment of the upper tusks in the female Dugong, and the persistent pulp-cavity and projection of the corresponding tusks in the male, are equally interesting repetitions of the phenomena manifested on a larger scale in the singular dental system of the Narwhal; but the habitual abrasion to which the tusks of the male Dugong are subject prevents their closer resemblance to the male Narwhal's tusk in regard to length. The simple implantation of the molar teeth and their composition are paralleled in the teeth of the Cachalot; their difference of form, and the more complex shape of the hindmost tooth, are repetitions of characters which were present in the dentition of the extinct *Zeuglodon*.

The co-existence of incisive tusks with molar teeth, and the successive displacement of the smaller and more simple anterior ones by the advance of larger and more complex grinders into the field of attrition, already seem to sketch out peculiarities of dentition, which become established and attain their maximum in the Proboscidean family (Elephants and Mastodons) of the Ungulate order.

The transition from the cetaceous to the more normal type of pachydermal dentition is effected by the Manatee (*Manatus*), especially by the modification of the molar series.

The deflected anterior extremities of the intermaxillary bones each support a single deciduous tusk in the young Manatee (fig. 69, i): but this is not succeeded by a permanent one in either sex. Six depressions for rudimental teeth

Order Sirenia.

Halicore.

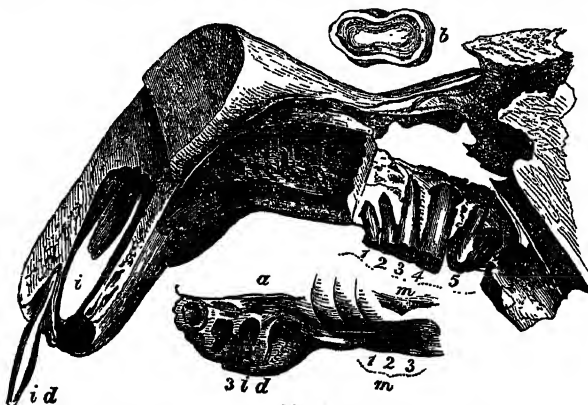

Fig. 67.
Section of Jaws and Teeth of a Dugong (*Halicore indicus*.)

from the gum in the male sex, and neither upper nor lower ones are visible in the female. The superior incisors (i) are two in number in both sexes. In the male they are moderately long, subtriangular, slightly and equally curved, of the same diameter from the base to near the apex, which is obliquely bevelled off to a sharp edge, like the scalpriform teeth of the *Rodentia*. Only the extremity of this tusk projects from the jaw, at least seven-eighths of its extent being lodged in the socket, the parietes of which are entire, and the exterior of the great intermaxillary bones presents an unbroken surface. In the female Dugong the growth of the permanent incisive tusks of the upper jaw is arrested before they cut the gum, and they remain throughout life concealed in the premaxillary bones; the tusk in this sex is solid, is about an inch shorter and less bent than that of the male; it is also irregularly cylindrical, longitudinally indented, and it gradually diminishes to an obtuse rugged point; the base is suddenly expanded, bent obliquely outwards, and presents a shallow excavation. The deciduous incisors of the upper jaw (fig. 67, i d) are much smaller than the permanent tusks of the female,² and are loosely inserted by one extremity in conical sockets immediately anterior to those of the permanent tusks (fig. 67), adhering by their

² Proceedings of the Zoolog. Society, 1838, p. 41.

Teeth of Mammals. occur in the gum, covering the deflected forepart of each ramus of the lower jaw in the young new-born American Manatee (fig. 68, 1-6), and in the sixth (6) Stannius¹ found a tooth, which he calls a sixth incisor.

The molars of the American Manatee are thirty-eight in number, ten on each side of the upper jaw, and nine, at least, on each side of the lower jaw; but they are never simultaneously in place and use. The number of teeth ordinarily in use at the same time is that represented in Fig. 69, 3-8, where the first and second molars (1, 2) have been shed, and the two last (9 and 10) have not come into place;

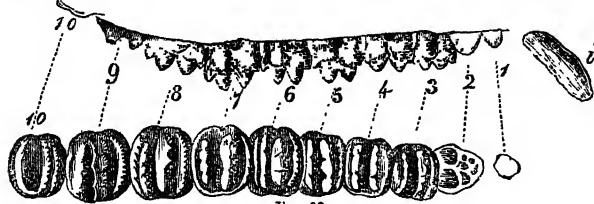

Fig. 69.

Teeth of the Upper Jaw of a Manatee.

in the lower jaw seven molars are usually in use in the adult. The first (figs. 68 and 69, 1) in both jaws is small and simple. Beyond the second, the crowns in the upper jaw are square, and support two transverse ridges with tri-tuberculate summits, having also an anterior and posterior basal ridge; each tooth is implanted by three diverging roots, one on the inner and two on the outer side; they increase in size very gradually, from the foremost to the last.

The crowns of the four or five anterior molars of the lower jaw resemble those above, but the rest have a large posterior tubercle; they are all implanted by two fangs, which enlarge as they descend, and bifurcate at the extremity; the crowns are of moderate height, and project only a few lines above the sockets.

The molars consist of a body of dentine, a coronal covering of enamel, and a general investment of cement, very thin upon the crown, and a little thicker upon the fangs.

All the grinding teeth of the Manatee belong to the true molar series, in so far as that none are displaced by vertical successors; but the first molar (fig. 68, 1) is small, conical, and simple, and is separated by a brief interval from the first of the two-ridged molars (2 e). In this respect the Manatee manifests, like the Dugong, a cetaceous character, and the more strongly, inasmuch as the number of molars successively developed from before backwards is greater. The anterior teeth are, however, displaced before the posterior ones are developed, although they have no vertical successors; which circumstance is also characteristic of the Elephant, and the shape, the structure, and the mode of implantation of the molars of the Manatee, accord with the pachydermal type, and herein more especially with the teeth of the *Dinotherium* and *Tapir*.

In the Marsupial order, the typical number of the teeth in the molar series is seven on each side of both jaws, the first three of which displace as many milk teeth, and are "premolars" (fig. 76, p 1, 2, 3), the other four are true "molars," (fig. 76, m 1, 4). Incisors (fig. 71, i) are present in all the species, but are variable in number, in some genera exceeding that of the Mammalian type. Canines (fig. 71, c) are large in the Dasyures, are feebly represented in the Phalangers and Petaurists, are absent in the lower jaw of the Potoroos and Koala, and in both jaws of the Kangaroos and Wombats.

The Dasyures and Thylacine offer the carnivorous type of the dental system, but differ from the corresponding group of the placental Mammalia, in having the molars of a more uniform and simple structure, and the incisors in greater number; the dental formula of the Dog-headed Opossum, *Thylacynus*, is—

$$\begin{matrix} i & 4.4 & c & 1.1 & pm & 3.3 & m & 4.4 \\ & 3.3 & & 1.1 & & 3.3 & & 4.4 \end{matrix} = 46.$$

The canine teeth are long, strong, curved, and pointed, like those of the dog tribe; the points of the lower canines are received in hollows of the premaxillary palatal plate when the mouth is closed, and do not project, as in the carnivorous placentals, beyond the margins of the maxillary bones. The premolars (p) present a simple compressed conical crown, with a posterior tubercle, which is most developed on the hindmost. The true molars (m) in the upper jaw are unequally triangular, the last being much smaller than the rest; the exterior part of the crown (fig. 70, a, b) is raised into one large pointed middle cusp and two smaller cusps; a small strong obtuse lobe (c) projects from the inner side of the crown. The

Fig. 70.

Penultimate Upper molar of the lower jaw are compressed and tri-cuspidate; the middle cusp being the longest, lacine. especially in the two last molars, which resemble closely the carnassial teeth (dents carnassières) of the dog and cat.

The dental formula of the genus *Dasyurus* is—

$$\begin{matrix} i & 4.4 & c & 1.1 & p & 2.2 & m & 4.4 \\ & 3.3 & & 1.1 & & 2.2 & & 4.4 \end{matrix} = 42.$$

The eight incisors of the upper jaw (fig. 70, i) are of the same

Teeth of Mammals. *Dasyurus*.

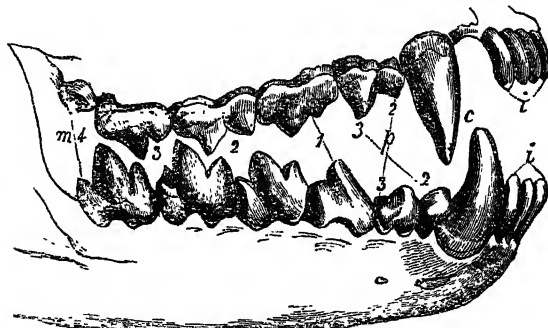

Fig. 71.

Dentition of the Ursine Dasyure. Nat. size.

length and simple structure, and are arranged in a regular semicircle. The six incisors of the lower jaw (fig. 71, i) are similarly arranged, but have thicker crowns than the upper ones. The canines (fig. 71, c) present the same, or even a greater relative development, than in the Thylacine; in an extinct species of *Dasyurus*, they had the same form and relative proportions as in the Leopard. The premolars (p 2 and 3) answer to the two last in the Opossum, and have simple crowns. The upper true molars (m) have triangular crowns; the first presents four sharp cusps; the second and third each five; the fourth, which is the smallest, only three. In the lower jaw, the last molar is nearly of equal size with the penultimate one, and is bristled with four cusps, the external one being the longest. The second and third molars have five cusps, three on the inner and two on the outer side; the first molar has four cusps. The carnivorous character of the above dentition is most strongly marked in the Ursine Dasyure, or *Devil* of the Tasmanian colonists, the largest existing species of the genus.

A carnivorous Australian marsupial, of the size of a Lion, *Thylacoleo* now extinct, which the writer determined under the name of *Thylacoleo carnifex*, in 1848, has a true carnassial tooth, upwards of an inch and a half in fore and aft extent, and one inch in height; consisting wholly of the "blade" in the lower jaw (fig. 72), and with the addition of a very feeble depressed tubercle in the upper jaw. On the occasion of a visit to London by M. Paul Gervais, at the period when the supposed marsupial character of the *Pterodon* or *Hynodon* (fig. 111) of the miocene deposits of Auvergne, Gard, and Vaucluse were under discussion, the writer took the opportunity to point out to that able comparative anatomist and palaeontologist, certain characters deducible from the foramen caroticum and foramen lacrymale, bearing on this question, and illustrated those conclusions by reference to the then unique carnivorous fossil which had a short time before been transmitted from Australia. M. Gervais accordingly enters the genus *Thylacoleo* in the geographical table of fossil mammalia, of the "Zoologie and Paléontologie Française," and in his remarks on those of Australia (Nouvelle Hollande), he writes, "Les dépôts pliocenes ou pleistocenes ont fourni des Grand Kangaroos, un grand Wombat,² divers autres espèces congénères de celles d'à présent, les genres de *Diprotodon* et *Nototherium*, qui étaient aussi des Marsupiaux, mais dont les allures et la taille approchaient de celles de nos grands pachydermes Diluviens, et le Dasyurien, plus grand que le Lion, que M. Owen nomme *Thylacoleo*" (p. 192).

Fig. 72.

Lower Carnassial Tooth, viewed from above, of the Thylacoleo.

In some of the smaller species of the carnivorous group, as the *Phascogale*, the canines lose their great relative size, and the molar teeth present a surface more cuspidated than sectorial; there is also an increased number of teeth, and as a consequence of their equable development, they have fewer and shorter interspaces. The genus *Phascogale* is characterized by—

$$\begin{matrix} i & 4.4 & c & 1.1 & p & 3.3 & m & 4.4 \\ & 3.3 & & 1.1 & & 3.3 & & 4.4 \end{matrix} = 46.$$

In this dental formula may be discerned a step in the transition from the Dasyures to the Opossums, not only in the increased number of spurious molars, but also in the shape and proportions of the incisors.

¹ Beitrage zur Kenntniss der Amerikanischen Manati's, 4to, Rostock, 1845.

² That, viz., which is alluded to as being "at least four times as large as either of the known existing species," in the writer's memoir on the extinct species of *Phascolomys*.—(July 1845), *Trans. Zool. Soc.* tom. iii. p. 306.

Teeth of
Mammals.Phascolo-
therium.

The general character of the dentition of these small predatory Marsupials approximates to the insectivorous type, as will be exemplified in the Shrew, Hedgehog, etc., among the placental Mammalia, and corresponds with the food and habits of the species, which thus lead from the predaceous, or flesh-feeding, to the Entomophagous tribes.

The interval is further diminished by a lost Marsupial genus, which forms one of the ancient Mammalia that have rendered the colitic formations at Stonesfield so famous. This genus, which the writer has called *Phascolotherium*,¹ presents the same numerical dental formula as in *Phascogale*, viz.—

$$\begin{matrix} i & p & c & m \\ \frac{4.4}{8.8} & \frac{1.1}{1.1} & \frac{3.3}{3.3} & \frac{4.4}{4.4} \end{matrix} \text{ (Fig. 73).}$$

But the incisors (*i*) and canines (*c*) are separated by vacant interspaces, and occupy a larger proportional space in the dental series.

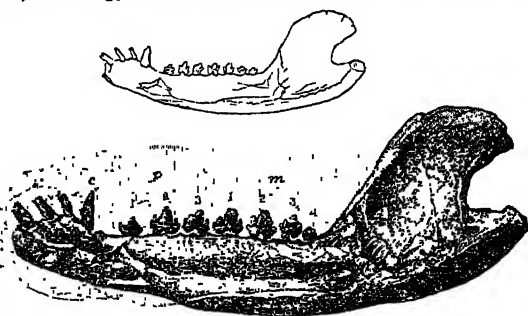

Fig. 73.

Lower Jaw and Teeth of the Phascolotherium. Nat. size, in outline.

The transition from the false (*p* 1, 2, 3) to the true (*m* 1, 2, 3, 4) molars, is more gradual; the latter are more compressed than in the Opossum; the five larger teeth present each a large middle cusp, with a smaller one in front and behind it, and with a basal ridge, which, projecting a little beyond both the anterior and posterior smaller cusps, gives a quinque-cuspid character to the crown of the tooth.

Myrmecobius.

The *Myrmecobius* (fig. 74) is characterised by the following remarkable dental formula:—

$$\begin{matrix} i & p & c & m \\ \frac{4.4}{8.8} & \frac{1.1}{1.1} & \frac{3.3}{3.3} & \frac{6.6}{6.6} \end{matrix} = 54.$$

From this formula it will be seen that the number of true and false molars, eighteen in both jaws, exceeds that of any other known existing Marsupial.

Fig. 74.

Dentition of the Myrmecobius.

The *Myrmecobius* (fig. 74) is characterised by the following remarkable dental formula:—

The genus *Amphitherium* is founded on fossil remains of lower jaws and teeth discovered, like those of the *Phascolotherium*, in the colitic slate at Stonesfield, in Oxfordshire, and it receives elucidation from the dental characters of the previous genus, but is remarkable for having a still greater number of molar teeth. The dental formula is as follows:—

$$\begin{matrix} i & p & c & m \\ \frac{4.4}{8.8} & \frac{1.1}{1.1} & \frac{3.3}{3.3} & \frac{6.6}{6.6} \end{matrix}$$

There being thus thirty-two teeth in the lower jaw, and probably as many in the upper jaw. The incisors (fig. 75, *i*) are small, simple,

Fig. 75.

Lower Jaw and Teeth of the Amphitherium. Twice nat. size.

and separated by intervals, as in the existing Marsupial genus *Myrmecobius*; the canine (*c*) had a similar form. The shape of the

crowns of the premolars (*p*) and molars (*m*) is shewn in the specimens of the larger species (*Amphitherium Broderipii*), in the museum at York, their implantation of the jaw, each by two long slender roots, as indicated in *m* 1 and 2, is demonstrated by one of the specimens of the smaller species (*Amphitherium Prevostii*) in the museum at Oxford.

Teeth of
Mammals.

The singular animal on which this genus was founded, has but two toes on each fore foot; its dental formula is—

$$\begin{matrix} i & p & c & m \\ \frac{4.4}{8.8} & \frac{1.1}{1.1} & \frac{3.3}{3.3} & \frac{4.4}{4.4} \end{matrix} = 46.$$

All the teeth are of small size; the upper incisors are conical, the lower ones truncated, and the hindmost is notched; the canines are conical and compressed; the upper one is simple and remote from the incisors; the lower one is near the incisors, and is notched anteriorly; the premolars are separated by intervals, as in *Myrmecobius*; they are tricuspid, except the first in the upper jaw, which resembles the canine. Each true molar consists of two triangular prisms, those of the upper jaw being broader than those below, and with their base turned outwards, contrary to those in the lower jaw. The genus would seem by its dentition to rank between *Myrmecobius* and *Perameles*. Its digital characters are anomalous and unique among the Marsupialia, but are evidently a degeneration from the Saltatorial or Bandicoot type.

The dental formula of the genus *Didelphys* is—

$$\begin{matrix} i & p & c & m \\ \frac{6.6}{4.4} & \frac{1.1}{1.1} & \frac{3.3}{3.3} & \frac{4.4}{4.4} \end{matrix} = 50 \text{ (Fig. 76).}$$

Didelphys.

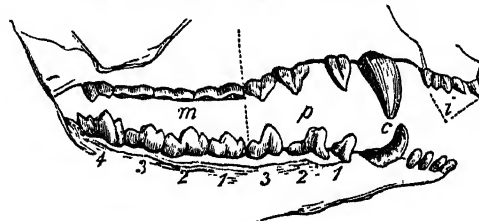

Fig. 76.

Dentition of the Virginian Opossum.

The Opossums resemble in their dentition the Bandicoots more than the Dasyures; but they closely resemble the latter in the tuberculous structure of the molars, the two middle incisors of the upper jaw are more produced than the others, from which they are also separated by a short interspace.

The canines still exhibit a superior development in both jaws adapted for the destruction of living prey, but the molars have a conformation different from that which characterizes the true flesh-feeders, and the Opossums consequently subsist on a mixed diet, or prey upon the lower organized animals.

The smaller species of *Didelphys*, which are the most numerous, fulfil in South America the office of the insectivorous Shrews of the old continent. The larger Opossums resemble in their habits, as in their dentition, the carnivorous Dasyures, and prey upon the smaller quadrupeds and birds; but they have a more omnivorous diet, feeding on reptiles and insects, and even fruits. One large species (*Did. Canivora*) prowls about the sea-shore, and lives, as its name implies, on crabs and other crustaceous animals. Another species, the Yapock, frequents the fresh water, and preys almost exclusively on fish. It has all the habits of the Otter; and, in consequence of the modifications of its feet, forms the type of the sub-genus *Chironectes*, Ill. Its dentition, however, does not differ from that of the ordinary Opossums.

The dental formula of the genus *Tarsipes* has not been accurately determined; the molars soon begin to fall; the small canines are also deciduous; the two procumbent incisors of the lower jaw remain the longest. The inferior incisors are opposed to six minute incisors above, which are succeeded by a small canine and some small molars; but these are reduced in some, perhaps old individuals, to a single tooth on each side.

The Phalangiers, being provided with hinder hands and prehensile tails, are strictly arboreal animals, and have a close external resemblance to the Opossums, by which name they are generally known in Australia and the islands of the Indian Archipelago, where alone they have hitherto been found. They differ from the Opossums chiefly in their dentition, and in accordance with this difference, their diet is more decidedly of a vegetable kind.

The absence of anomalous or functionless premolars, and of Phascoid inferior canines, appears to be constant in this genus, the dental formula of which, in other respects resembles that of *Phalangista*; it is—

$$\begin{matrix} i & p & c & m \\ \frac{3.3}{1.1} & \frac{1.1}{0.0} & \frac{1.1}{1.1} & \frac{4.4}{4.4} \end{matrix} = 30 \text{ (Fig. 77).}$$

The true molars (fig. 77) are larger in proportion than in the Phalangiers; each is beset with four three-sided pyramids (*a, b, c, d*), the cusps of which wear down in age, the outer series in the upper

¹ Transactions of the Geological Society of London, vol. vi. 2d series, 1838, p. 58, pl. 6.

Teeth of Mammals. teeth being the first to give way; those in the lower jaw are narrower than in the upper; there is also the rudiment of a "cingulum,"

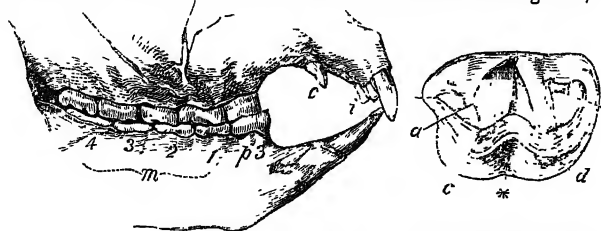

Fig. 77. Molar Tooth of the Koala magnified.

Dentition of the Koala (*Phascolarctos fuscus*.) as at **. The premolars (*p* 3) are compressed, and terminate in a cutting edge; in those of the upper jaw there is a small parallel ridge along the inner side of the base. The canine (*c*) slightly exceeds in size the posterior incisor, and terminates in an oblique cutting edge rather than in a point; the fang is closed at the extremity; it is situated, as in the Phalangians, close to the premaxillary suture. The lateral incisors of the upper jaw are small and obtuse; the two anterior or middle incisors are more than twice as large as the rest; they are conical, slightly curved, sub-compressed, bevelled off obliquely to the anterior cutting edge, but differing essentially from the *dentes scalprarii* of the Rodentia in being closed at the extremity of the fang. The two incisors of the lower jaw resemble those of the upper, but are longer and more compressed.

The dental formula of *Hypsiprymnus*, the generic name of the Potoroo, or Kangaroo-rats, is—

$$\begin{matrix} i & 3.3 & c & 1.1 & p & 1.1 & m & 4.4 \\ \hline & 1.1 & & 0.0 & & & & \end{matrix} = 30$$

The anterior of the upper incisors, (fig. 78, *i*) are longer and more curved than the lateral ones, and their pulps are persistent. The canine (*c*) is larger than in the Koala; it is situated on the line of the premaxillary suture; and while the fang is lodged in the maxillary, the crown projects almost wholly from the premaxillary bone. In the large *Hypsiprymnus ursinus*, the canines are relatively smaller than in the other Potoroo, a structure which indicates the transition from the Potoroo to the Kangaroo genus. The single premolar (fig. 78, *p*) has a peculiar trenchant form; its maximum of development is attained in the arboreal Potoroo of New Guinea (*Hypsiprymnus ursinus* and *Hypsiprymnus dorcocephalus*), in the latter of which its antero-posterior extent nearly equals that of the three succeeding molar teeth. In all the Potoroo, the trenchant spurious molar (*p*) is indented, especially on the outer side, and in young teeth, by many small vertical grooves. The true molars (*m* 1, 2, 3, 4) each present four three-sided pyramidal cusps; but the internal angles of the two opposite cusps are continued into each other across the tooth, forming two angular or concave transverse ridges. In the old animal these cusps and ridges disappear, and the grinding surface is worn quite flat.

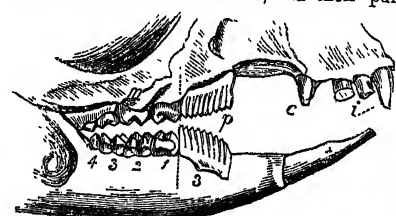

Fig. 78. Dentition of the Potoroo, (*Hypsiprymnus*.)

In the genus *Macropus* (fig. 143), the normal condition of the permanent teeth may be expressed as follows:—

$$\begin{matrix} i & 3.3 & c & 0.0 & p & 1.1 & m & 4.4 \\ \hline & 1.1 & & 0.0 & & & & \end{matrix} = 28.$$

The main difference, as compared with *Hypsiprymnus*, lies in the absence of the upper canines as functional teeth; but the germs of these teeth are always to be found in the young mammary fetus of the *Macropus major*, and the writer has detected them, but of very small size, and concealed by the gum, in the adults of some small species of Kangaroos, as, e.g., *Macropus rufiventris*, Ogilby, and *Macr. psilopus*, Gould. This, however, is a rare exception; while the constant presence and conspicuous size of the canines will always serve to distinguish the Potoroo from the Kangaroo. The crown of the true molars supports two principal transverse ridges, with a broad anterior talon and a narrow hinder one. In most species a spur is continued from the hinder to the fore ridge, and another from the fore ridge to the front talon.

Dr Mason Good has remarked, "The *Mus maritimus*, or African rat, has the singular property of separating at pleasure, to a considerable distance, the two front teeth of the lower jaw, which are not less than an inch and a quarter long; that elegant and extraordinary creature, the Kangaroo, which, from the increase that has lately taken place in his Majesty's garden at Kew, we may soon hope to see naturalized in our own country, is possessed of a similar faculty."

This faculty of divaricating the lower incisors is due to the laxity of the symphyseal union of the two rami of the lower jaw; the teeth merely move with the bones in which they are implanted. Remains of gigantic Kangaroos have been discovered in the same caves in Australia which contained the teeth and jaws of the large extinct *Dasyurus lanarius*, and they probably formed the prey of that species and of its contemporary the Thylacine, which has equally become extinct in the continent of Australia.

A gigantic extinct herbivorous Australian Marsupial, the bulk of which may be surmised from the length of the skull, which equals three feet, manifests a dentition which makes the nearest approach to the type of the Kangaroos; but the anterior or median pair of upper incisors of the upper jaw present the condition of large, curved, scalpriform, over-growing tusks, which work against a similar but straight procumbent pair of incisive tusks below; thus presenting a transitional feature between the Kangaroos and the Rodent form of Marsupial called Wombat (*Phascolomys*).

By reason of this modification, the writer separated the above large fossil Marsupial generically from *Macropus*, and proposed for it the name of Diprotodon, or two-incisored, in his Description of the Australian fossil Mammalia, in the appendix to "Mitchell's Expedition into the Interior of Eastern Australia," 8vo, 1838.

He has since ascertained that the second and third incisors are present, though of diminutive size, in the upper jaw of the Diprotodon; but as these teeth are actually reduced to two in the lower jaw, and functionally so in the upper one, the generic name is still applicable. There is no trace of canines in either jaw. The molars present the double transversely-ridged type of the *Macropus*, an anterior and posterior low basal ridge being added to the two principal eminences.

Five such molars were developed on each side of both jaws, progressively increasing in size from the first to the fourth. The first is generally shed before the last is in place.

A second genus of huge Marsupial Herbivora has been indicated under the name of *Nototherium*.² The *Thylacoleo* seems to have been designed to keep these giants of the order in check.

The dental system presents, in fig. 79, the extreme degree of Phascolomys.

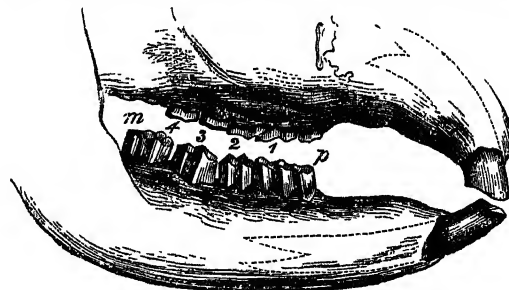

Fig. 79. Dentition of the Wombat (*Phascolomys*.)

that degradation of the teeth, intermediate between the front incisors and true molars, which has been traced from the Opossum to the Kangaroos; not only have the functionless premolars and canines now totally disappeared, but also the posterior incisors of the upper jaw, which we have seen in the Koala and Potoroo to exhibit a feeble degree of development as compared with the anterior pair; these, in fact, are alone retained in the dentition of the genus *Phascolomys*.

The dental formula of the Wombat is thus reduced, both in number and kind, to that of the true Rodentia, viz.—

$$\begin{matrix} i & 2 & c & 0 & p & 1.1 & m & 4.4 \\ \hline & & & & & & & \end{matrix} = 24 \text{ (Fig. 79).}$$

The incisors (*i*), moreover, are *dentes scalprarii*, with persistent pulps; but are inferior, especially in the lower jaw, in their relative length and curvature to those of the placental *Glires*; they present a subtriangular figure, and are traversed by a shallow groove on their mesial surface. The premolars (*p*) present no trace of that compressed structure which characterises them in the Koala and Kangaroos, but have a wide oval transverse section; those of the upper jaw being traversed, on the minor side, by a longitudinal groove. The true molars (*m* 1-4) are double the size of the premolars; the superior ones are also traversed by an internal longitudinal groove; but this is so deep and wide that it divides the whole tooth into two prismatic portions, with one of the angles directed inwards. The inferior molars are in like manner divided into two triangular portions, but the intervening groove is here external, and one of the facets of each prism is turned inwards. All the grinders are curved, and describe about a quarter of a circle. In the upper jaw the concavity of the curve is directed outwards; in the lower jaw, inwards. The false and true molars, like the incisors, have persistent pulps, and

Teeth of Mammals.

are, consequently, devoid of true fangs, in which respect the Wombat differs from all other Marsupials, and resembles the extinct *Toxodon*, the dentigerous *Bruta*, and herbivorous *Rodentia*.

The cuts, figs. 72, 70, 77, and 80, showing the working surface of the molar teeth, exemplify stages in the progressive transition from the carnivorous to the herbivorous modification of those teeth in the Marsupial series.

Figure 72, nat. size, is the lower carnassial tooth of the great extinct *Thylacoleo*. Fig. 70 is an upper molar of the largest existing Marsupial carnivore, the Thylacine of Tasmania; the addition of the inner lobe (c) gives it a triangular form. In the *Dasyurus* the inner lobe is augmented, and the outer division is thickened by the development of a pointed tubercle or cusp from the cingulum. In the Bandicoot (*Perameles Myosuros*), a second lobe answering to *d* in fig. 77 is added to the inner division of the crown, and two tubercles are developed from the outer part of the cingulum; in the *Phalangista* and Koala (fig. 77), the outer tubercles are obsolete, and the principal lobes (a, b, c, d) are almost equal, with a posterior basal ridge and the rudiment of an anterior one.

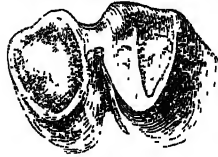

Fig. 80.

Grinding Surface of a Lower Molar (nat. size) of the Great extinct Wombat.

cut is taken from a molar tooth of the lower jaw of the great extinct *Phascologomys gigas*.

Order Insectivora.

The dental system in this order is remarkable for the many varieties and even anomalies which it presents—almost the only characteristic predicable of it in the numerous small quadrupeds which constitute it being the presence of several sharp points or cusps upon the crowns of the molar teeth, which are always broader in the upper than in the lower jaw. The teeth that intervene between these and the incisors are most variable in form and size, but are never absent;

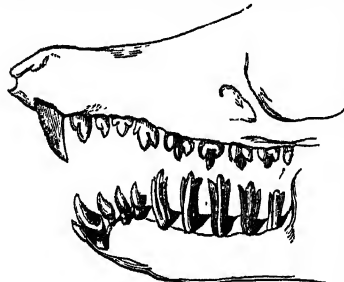

Fig. 81.

Dentition of the Cape-Mole (*Chrysochloris capensis*) magnified.

the incisors also differ in number, size, and shape, in different species, the anterior ones approximating in some species to the character of the scalpriform teeth of the Rodents. Of all existing *Insectivora*, the Chrysochlore, or iridescent mole of the Cape, makes the nearest approach, by the number of its molar teeth (fig. 81), to that remarkable condition which was manifested in the most ancient period of Mammalian existence by the extinct *Amphitherium* and *Spalacotherium* of the Oolitic period in geology. At least $3\frac{1}{2}$ true molars may be assigned to the Chrysochlore according to their form—the only character, in the absence of the known order of vertical displacement and succession by which the true and false molars can at present be defined in this species. The anterior large laniform tooth, and the two succeeding small teeth, are incisors, by virtue of their position in the premaxillary bones; the next small tooth, with a simple compressed tricuspid crown, may be regarded either as a canine or a premolar. The crowns of the true molars are thin plates, flattened from before backwards, with two notches on the working edge, and a longitudinal groove along the outer and thicker margin. Another anomaly, more remarkable than that of the shape of the true molars, is their separation from each other by vacant intervals, as in many Reptiles.

The crowns of the five lower true molars are compressed antero-posteriorly, but are of unusual length, and have the thicker margin turned inwards; the summit of the outer border is pointed and most prominent; the inner division is subdivided into two points. The anterior incisor is small and procumbent; the second has a larger laniform crown; the third is small, and resembles the two premolars which intervene between this and the first large tricuspid molar. The lower molars are separated by wider intervals than those above; the crowns of the opposing series enter reciprocally the interspaces, and interlock; in mastication, the anterior margin of the lower tooth works upon the posterior margin of the opposite upper tooth.

According to M. Cuvier,¹ each series in the upper jaw of the Chrysochlore includes one incisor and nine molars; and in the lower jaw two incisors and eight molars. M. de Blainville, guided by the intermaxillary sutures in the young Chrysochlore, regards the first three teeth in each lateral series as incisors, the fourth as a canine, and the remaining six as molars in both upper and lower jaws. The writer's views, as given in the foregoing description, are expressed by the following formula—

$$i \frac{3.3}{5.3}; p \frac{1.1}{2.2}; m \frac{6.6}{5.5} = 40.$$

The small insectivorous mammal, called *Spalacotherium*,² which has left its fossil remains in the upper Oolite of Purbeck, had ten molar teeth on each side of the lower jaw, of which six at least presented a tricuspid crown (fig. 82), with proportions very similar to those of the Chrysochlore.

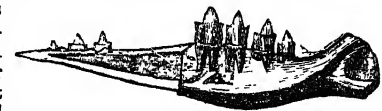

Fig. 82.

Part of Lower Jaw and Teeth of the *Spalacotherium tricuspidens*.

In the Shrew-moles of America (*Scalops*) the dentition makes an important step towards the normal mammalian condition, by the restriction of the characters of the true molar teeth to the three posterior ones in each lateral series; between these and the large scalpriform incisor, in the upper jaw, there are six teeth; the first two of which must also be regarded, by the analogy of the Chrysochlore, as incisors; the next tooth might pass for a canine; and the remaining three for premolars; of these the last is the largest, and has a triadial pointed crown. The true molars have large crowns, each with six cusps, four on the outer, and two on the inner part of the grinding surface. In the lower jaw the first incisor is small and procumbent, and the second large and laniform, as in the Chrysochlore; the third is absent, and a vacant space separates the incisors from the three premolars, and the crown of each true molar consists of two parallel three-sided prisms, each terminated by three cusps, and having one of the angles turned outwards, and one of the faces inwards; the interspaces between the angles makes the outer surface of the long molars of the *Scalops* appear grooved. The dental formula of this genus, according to the above description, is—

$$i \frac{3.3}{2.2}; c \frac{1.1}{0.0}; p \frac{3.3}{3.3}; m \frac{3.3}{3.3} = 36.$$

The dentition of the common mole (*Talpa europæa*, fig. 83) Talpa.

includes eleven teeth on each side of both upper and lower jaws. The first three in the upper jaw are very small, with simple incisive crowns, and are each implanted by a long and slender fang. These teeth are incisors. The next tooth (c), by the size and shape of the crown, represents a canine, but it is implanted by two fangs like the succeeding premolar teeth. Three of these teeth (p 1, 2, 3) are of small size, with compressed conical crowns; the fourth premolar (p 4) has a larger three-sided conical crown, supported by three fangs, the crowns of the true molars (m 1, 2, 3) are multicuspoid; the middle one the largest, with five points, and usually supported by four fangs, the hindmost the smallest, with a tricuspid crown and three fangs. In the lower jaw the first four teeth on each side are small, simple, and single-fanged, like the three incisors above; the fifth tooth has a large laniform crown, supported by two fangs, being very similar to, but shorter than, the two-fanged canine above. As it passes behind that tooth when the mouth is shut, we must regard the fourth tooth below, notwithstanding its small size and similarity to the incisors, as the true inferior canine, as it is in the Ruminants. The fifth tooth (p 1) is then the first and largest of the series of four premolars, each of which has a small posterior talon at the base of the compressed conical crown. The three true molars (m 1, 2, 3) are each implanted by two fangs, and have quinque-cuspid crowns, the middle molar being the largest.

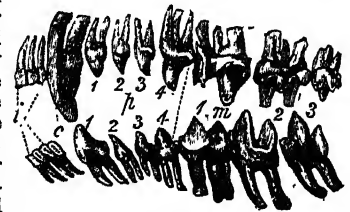

Fig. 83.

Dentition of the Mole (*Talpa europæa*).

The teeth of the mole have been differently classified by different authors; but the difference turns mainly upon the determination of the canine teeth. F. Cuvier³ and T. Bell⁴ both regard the fourth large tooth of the upper jaw (c) as a canine, notwithstanding it has two fangs. M. de Blainville⁵ describes it as an incisor, in which case the double implantation would be still more anomalous. The position of the incisive foramen, however, indicates that the double socket of this tooth is posterior to the premaxillary suture, and that the number of incisors has been rightly determined by F. Cuvier.

⁵ *Osteographie, Insectivores*, 4to, p. 49.

Teeth of
Mammals.

By this justly-esteemed authority, the canines are held to be wanting in the lower jaw of the mole. Mr Bell regards as lower canines the large fifth tooth on each side, although posterior to the canine above; and M. de Blainville, having assigned eight incisors to the upper jaw, adopts the same view in regard to the lower jaw, and calls the first premolar (*p* 1) a canine. With regard to the fourth tooth above, if it be not developed in the premaxillary bone, it claims to be regarded as a canine by the size and shape of the crown, and to be a premolar by virtue of its two fangs; but, since the fang of a tooth is subject to more variety than the crown, the present writer has been guided by the more fixed character, and has called the tooth in question a canine.¹ The fourth tooth below (*c*), although so small, is the only one which has the true relative position of a canine, in advance of the one above when the mouth is shut, and we shall find in the genus *Lemur* a similar conformity of size and shape between the lower canine and incisors as exists in the common mole.² There is no difficulty about the other teeth, the canines being determined, and thus the dental formula of the genus *Talpa* is—

$$i \frac{3.3}{3.3}; c \frac{1.1}{1.1}; p \frac{4.4}{4.4}; m \frac{3.3}{3.3} = 44.$$

According to this homology, the teeth are equal in number, and alike in kind in both jaws; the true molars are reduced to the normal quantity in the placental series, and the entire dentition is the least anomalous of any which is manifested in the family *Talpidae*.

In the *Talpa moogura*, Temm., the inferior canine is absent, as in the genus *Scalops*. In the *Condylure*, or Rayed-mole, it is present, with the form and proportions of a canine.

In *Talpa leucura*, Blyth (*p* 1), is wanting.

Soricidae.
Solenodon.

The transition from the Moles to the Shrews seems to be made by the water-moles (*Mygale*), and the *Solenodon*. The latter insectivore combines the form of a gigantic Shrew, with a dentition resembling that of the *Chrysochlore*. Each premaxillary bone contains three incisors, the first large, canine-shaped, grooved anteriorly, with the point inclined backwards; the other two incisors small, with simple conical crowns; these are succeeded by seven teeth, the two anterior having three-sided conical crowns, the other five bearing, in addition, an external tuberculate basal ridge. In the lower jaw, the anterior incisor is very small, and the second large and lanariiform, as in the *Scalops* and *Chrysochlore*; but it is remarkable for a deep longitudinal excavation upon its inner side,³ apparently produced by the friction of the large upper incisors which are received into the interspace of the lower pair; the third lower incisor is small and simple; of the seven succeeding teeth, the four last have multicuspid crowns like true molars.

Mygale.

The Pyrenean Water-mole (*Mygale pyrenaica*) has eleven teeth on each side of both jaws; the first incisor above is relatively larger than in *Scalops*, trihedral, and sharp-pointed; the second and third incisors are very small; none of the succeeding teeth present the form and size of a canine; the last three teeth are multicuspid, and are true molars. In the lower jaw, all the teeth anterior to the true molars are small and simple.

The teeth in the lower jaw of a species of Water-mole (*Palaeospalax*), as large as a Hedgehog, which has become extinct in England, present a close resemblance with those of the *Mygale*; the true molars have square, quinque-cuspid crowns, but are distinguished from the teeth of all known recent *Insectivora* by the presence of a minute tubercle at the bottom of the outer vertical fissure of the crown.⁴

The typical Shrews always manifest their rodent analogy by the great preponderance of the anterior pair of incisors in both upper and lower jaws. In the lower jaw the great incisor is uniformly succeeded by two small and three large multicuspid molars; but in the upper jaw the number of small premolars varies. The last true molar is commonly of small size. The subgenera of Shrews are chiefly based upon the form of the large incisors and the numerical variations of the dentition of the upper jaw. In the common Shrew (*Sorex araneus* of Linnæus) there are four true molars and three small teeth between these and the anterior incisor; this tooth has a pointed tubercle at the back of the base of the crown. The long procumbent incisor of the lower jaw has the trenchant superior margin entire. In the *Sorex* (*Amphisorex*) *tetragomurus*, the upper edge of the lower incisor is notched; the large upper incisor appears bifurcate from the great development of the posterior talon; five small teeth, progressively decreasing in size, intervene between the upper large incisor and the true molars. In the *Sorex* (*Hydrosorex*) *Hermann*, the trenchant edge of the lower procumbent incisor is entire; there are four small teeth between the large anterior incisor and the true molars in the upper jaw, as in the great *Sorex indicus*; but the three first are subequal, and the fourth very minute; there is a fourth small true molar above. The enamelled tips of the teeth

of the species of *Amphisorex* and *Hydrosorex* are stained of a bright brown colour; the teeth of *Sorex* proper, as the common Shrew (*S. araneus*), are not so stained.

Teeth of
Mammals.

In the progress of the formation of the large notched incisors, the summits of the tubercles are first formed as detached points, supported upon the common pulp, and do not become united until the centripetal calcification has converted this into a common dental base. Some anatomists have regarded the large incisor so formed as an aggregate of two or three teeth; but in *Sorex* proper and *Hydrosorex*, the calcification of the lower incisor spreads from a single point, and the interpretation of the notched incisor of the *Amphisorex*,⁵ as the representative of these incisors, might, by parity of reasoning, be applied to the human incisor teeth, the dentated margins of which are likewise originally three or four separate tubercles.

The determination of the small teeth between the large anterior incisors and the multicuspid molars depends upon the extent of the early ankylosed premaxillaries; the incisors being defined by their implantation in those bones, the succeeding small and simple-crowned molars must be regarded as premolars; not any of them having the development or office of a canine tooth; their homotypes in the lower jaw are implanted by two roots.

The thickness of the enamel, in proportion to the body of dentine, is unusually great in these small insectivores, and the sharp points of the teeth long retain their fitness for the office of cracking and crushing the hard or tough teguments of insects.⁶ The enamel-pulp of the large lower incisors is so large as to overlap, in the young Shrew, the growing margin of the socket, so as to encase with enamel not only the crown of the tooth, but also the contiguous part of the jaw-bone. Daubenton first drew attention to this structure, and M. Duvernoy has likewise made the interesting observation, that the roots of the teeth of Shrews become ankylosed to the jaw-bone, a reptilian character offered by the *Soricidae* alone in the mammalian class.

In the dentition of the Tupaia (*Glisorex*) we begin to trace *Erinaceida*. characters intermediate between those of the dentition of Shrews *Glisorex*. and of Hedgehogs. The dental formula of the *Glisorex tana* is—

$$i \frac{2.2}{2.2}; c \frac{1.1}{1.1}; p \frac{3.3}{3.3}; m \frac{3.3}{3.3} = 36.$$

The upper incisors are small, simple, and wide apart in the upper jaw; the anterior incisor in the lower jaw is long and procumbent, but relatively smaller than in the Shrews; the canines are small in both jaws; the premolars increase in size and complexity as they approach the true molars; the first two of these are subequal, with six cusps in the upper and five cusps in the lower jaw; the last true molar is smaller, and is tricuspid.

In *Macroscelis* (Elephant-mice of the Cape) and *Gymnura*, each intermaxillary bone contains three teeth, which, in the former genus, are succeeded by four premolars and three true molars, with the same number of teeth in the lower jaw. In *Gymnura* (fig. 84) the first tooth which succeeds the incisors has the form and size of a canine (*c*) in both upper and lower jaws, but has two roots in the upper jaw; this is followed by four premolars (*p* 1-4), the last of which, in the upper jaw, is large and quadricuspid, the first (*m* 1) and second (*m* 2) of the true molars have square multicuspid crowns; the last true molar (*m* 3) is smaller and triangular. In the lower jaw of the *Gymnura* the fourth premolar (*p* 4) has a compressed tricuspid crown. The dental formula of *Gymnura* is typical, viz.—

$$i \frac{3.3}{3.3}; c \frac{1.1}{1.1}; p \frac{4.4}{4.4}; m \frac{4.4}{4.4} = 42.$$

The dentition of our common Hedgehog (*Erinaceus europæus*) shows greater inequality in the upper and lower jaws, the formula being—

$$i \frac{3.3}{3.3}; p \frac{4.4}{2.2}; m \frac{3.3}{3.3} = 36.$$

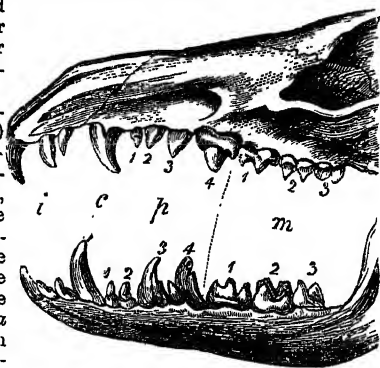

Fig. 84.

Dentition of the *Gymnura Rafinesii*.

¹ *Odontography*, 1842, p. 416. Mr Blyth has arrived, as it seems independently, at the same conclusion. He writes: "In the moles, as in most other *Insectivora*, and also in the *Lemuridae*, the lower canine is minute, and takes the form of an incisor, for which it has been very commonly mistaken, and the first premolar is developed to assume the form of a canine." *Journal of the Asiatic Society*, No. 3, 1850.

Teeth of Mammals.

The first incisor in both upper and lower jaws is larger and longer than the rest, and is very deeply implanted in the jaw; the tooth which follows the incisors is small in both jaws, but especially so in the lower; it has two roots in the upper jaw. The last premolar is the largest in both jaws; above it has a quadricuspid crown with three fangs; below, a subcompressed tricuspid crown with two fangs. The true molars decrease in size from the first to the third in both jaws, the first and second have subquadrate four-pointed crowns above; below, they are narrower, and the anterior and inner angle is produced into a fifth cusp.

The true molars of the tropical Hedgehogs, forming the sub-genera *Echinops* and *Ericulus*, are more simple, and approach the form of those in the Chrysochlore, being compressed from before backwards, with two outer cusps and one inner cusp in the upper jaw, and with one outer and two inner cusps in the lower jaw. The number of incisors is $\frac{2}{2}$ in both sub-genera, which are followed by $\frac{2}{2}$ small and simple premolars; but *Ericulus* has $\frac{2}{2}$ compressed tricuspid molars, and *Echinops* only $\frac{4}{4}$.¹

Centetes.

The large Tenrecs or tailless Hedgehogs of Madagascar, combine the simple molars of the *Ericulus* with the most formidably developed canines which are to be met with in the whole order *Insectivora*. The incisors are two in number in the upper jaw, but three in the lower jaw; very small and sub-equal in both; the canines are long and large, compressed, trenchant, sharp-pointed, recurved, and single-fanged, thus presenting all the typical characters of those teeth in the *Carnivora*. They are separated in both jaws by a wide space from the premolars; the first above is compressed, unicuspid with a hinder talon, and two-fanged; the second has a larger prismatic tricuspid crown and three fangs; of the four posterior teeth, which by their antero-posterior compression may be regarded as true molars, the first three have tricuspid crowns as in the *Echinops*, and have three fangs; the fourth is smaller, is tricuspid, and has two fangs; all the lower molars have two fangs.

Structure.

The teeth of the insectivora consist of a basis of hard dentine, with a thick coronal investment of enamel, and an outer covering of cement, very recognizable in the interspaces of the coronal cusps, in microscopic sections of the molars of the larger species, as the Tenrecs and Macroscelles, and always thick where it closes the extremity of the fangs. Here the cement is commonly more highly organized, is traversed by medullary canals, generally presenting concentric walls, thus assumes the character of true bone, and, in the *Soricidae*, is frequently continued into the substance of the jaw itself.

The small proportion of dentine, in comparison with the thick layer of enamel, has been already alluded to in the Shrews, yet the dentinal tubuli are at their commencement very little inferior in diameter to those of the human incisors; the trunks are very short, and are resolved into radiated penicilli of undulating branches, which quickly subdivide, interlace and anastomose together near the boundary line between the dentine and enamel. In most of the *Insectivora*, the secondary branches of the dentinal tubes are unusually conspicuous, especially in the dentine forming the fangs. The dentinal compartments are rarely well defined; in the large canines of the *Centetes*, they are sub-hexagonal, and about $\frac{1}{1000}$ th of an inch in diameter, but diminish in size towards the periphery of the dentine.

Development.

The deciduous teeth of the Moles and Shrews are uterine, i. e., are developed, and disappear before birth. They are extremely small, and are all of the most simple form. In the fetal *Sorex araneus*, calcification of the papillary exposed pulps of the teeth, which are succeeded by the first and second premolars, proceed to a very slight extent, and these microscopic rudiments appear to be absorbed rather than shed. The deciduous incisors are further advanced before their displacement, and present the form of equal-sized dentinal spicula, tipped with enamel, attached by the opposite end to the gum, and not exceeding $\frac{1}{10}$ th of an inch in length; the number of the uterine series of teeth is $\frac{4.4}{3.5}$.

Order Cheiroptera.

In the volant *Insectivora*, or Bats, the canines are always present in both jaws, of the normal form, and with slightly variable proportions. The molar series never exceeds $\frac{6.5}{6.5}$, and is divisible into premolars and true molars; the latter are bristled, with sharp points, and this type characterises the great bulk of the *Cheiroptera* of Cuvier. The molars of the large frugivorous Bats (*Pteropus*) have flat crowns.

The incisors are the most variable teeth in the *Cheiroptera*; they may be entirely wanting, or be present in the numbers of 1.1 to 2.2 in the upper, and from 1.1 to 3.3 in the lower jaw; they are always very small, and, in the upper jaw, commonly unequal, and separated by a wide median vacancy. In the genus *Chilonycteris*, the mid-incisors above, and the outer ones below, have the crown notched; the mid-incisors below have two notches, producing three lobes on

the cutting border. Taking the common simple-nosed Bat (*Vesperugo murinus*) as a type of this Insectivorous group, we find its dental formula to be—

$$\frac{2.2}{3.3}; c \frac{1.1}{1.1}; p \frac{3.3}{3.3} = 38.$$

Teeth of Mammals.

The dentition of the suctorial or Vampire Bats deviates, as might be anticipated, in a remarkable degree from that of the Insectivorous Bats. The crushing instruments required for the food of those species are not needed; and the true molars, with their bristled crowns, are entirely absent in the Vampires (*Desmodus*), (fig. 85). The teeth, at the fore-part of the mouth, are especially developed, and fashioned for the infliction of a deep and clean triangular puncture, like that made by a leech. The incisors are two in number above, closely approximated, one in each premaxillary bone, with a very large, compressed, curved, and sharp-pointed crown, implanted by a strong fang which extends into the maxillary bone. The upper canines have similar large lancet-shaped crowns, and their bases touch those of the incisors. In the lower jaw the incisors are two in number on each side, much smaller than the upper pair, and with bilobed crowns. The lower canines are nearly equal in size to those above, and have similar piercing trenchant crowns. The molar series is reduced above to two very small teeth, each with a simple compressed conical crown, implanted by a single fang. The first two molars below resemble those above; but they are followed by a third, which has a larger compressed and bilobed crown, implanted by two fangs. This tooth corresponds with the last premolar in the more normal genera of Insectivorous Bats. The dental formula of the true Vampire Bat (*Desmodus*), is thus reduced to—

$$\frac{1.1}{2.2}; c \frac{1.1}{1.1}; p \frac{2.2}{3.3} = 20.$$

Fig. 85.

Skull and Teeth of the Vampire-Bat (*Desmodus Fampirus*).

The opposite extreme which the aberrant varieties of the Chei- Pteropus, roperous dentition attain, is manifested in the great frugivorous Bats—sometimes, but erroneously, called Vampires—but which have never been met with in South America, the peculiar country of the true blood-sucking Bats.

The complex stomach of a *Pteropus* is described as that of a Vampire Bat in the "Lectures of Comparative Anatomy," by Sir Everard Home, who thereupon infers that "the Vampire Bat lives on the sweetest of vegetables," and that "all the stories related with so much confidence of its living on blood, and coming in the night to destroy people while asleep, are entirely fabulous," p. 160. But the blood-thirsty habits of the true Vampires have been observed or experienced by more than one scientific traveller in South America. Dr Spix calls one of these Bats, which he discovered in Brazil, "*Sanguisuga crudelissima*," and Mr Darwin has recorded the attack of another species which fastened upon the withers of his horse during a nocturnal bivouac in Chili.²

In some African *Pteropi* (*Pt. macrocephalus* and *Pt. Whitei*), the last small molar would seem to be wanting in both upper and lower jaws, according to Messrs Ogilby and Bennett.³

The frugivorous species, sometimes called "flying foxes," and by the French "Rousettes," include the largest animals of the order *Cheiroptera*, and constitute the genus *Pteropus*; their dental formula is—

$$\frac{2.2}{2.2}; c \frac{1.1}{1.1}; p \frac{2.2}{3.3}; m \frac{3.3}{3.3} = 34.$$

The deciduous teeth make their appearance above the gum in Bats, as in Shrews, before birth; but they attain a more completely developed state, and are retained until a short time after birth, when they are shed.

The Colugos (*Galeopithecus*) resemble the Bats in the great Galeopithecus. expanse of their parachute, formed by the fold of integument extending on each side from the fore to the hind extremity; but they appertain, by the essential characters of their organization, to the *Lemuridae*; the dental formula of the genus is—

$$\frac{2.2}{3.3}; c \frac{1.1}{1.1}; p \frac{2.2}{2.2}; m \frac{3.3}{3.3} = 34.$$

The two anterior incisors of the upper jaw are separated by a wide interspace; in the Philippine Colugo they are very small, with simple bilobed crowns; but in the common Colugo (*Lemur volans*, Linn; *Galeopithecus Temminckii*, Wat.) their crown is an expanded plate, with three or four tubercles; the second upper incisor, which is unquestionably supported by the intermaxillary bone, presents the peculiarity of an insertion by two fangs in both species of *Galeopithecus*.

In the lower jaw the crowns of the first two incisors present the

Teeth of Mammals.

Structure.

Fig. 86.

Lower Incisor of *Galeopithecus*. Magn.

Order Rodentia.

form of a comb, and are in this respect unique in the class *Mammalia*; one is figured magnified three diameters in cut 86. This singular form of tooth is produced by the deeper extension of the marginal notches on the crown, analogous to those on the edge of the new-formed human incisor; the notches being also more numerous as well as deeper; each of these teeth is implanted by a single conical fang.

In the broad pectinated incisors of the *Galeopithecus* the pulp-cavity divides at the base of the crown into as many canals as there are divisions of the crown, one being continued up the centre of each to within a short distance of its apical extremity. The dentinal tubes which radiate from these canals have a diameter at their origin of $\frac{1}{15,000}$ th of an inch; they quickly divide and subdivide dichotomously, with rather large and irregular secondary undulations, sending off many fine branches, and resolving themselves into numerous smaller ramifications which interlace irregularly near the enamel.

In different orders of the class *Mammalia*, there are instances in which the ordinary number of incisors is diminished, and their growing power transferred to a single pair of tusks projecting from the forepart of the upper or the lower jaw, or of both. The *Dinotheres*, *Toxodons*, *Mastodons*, and *Elephants*, among the *Ungulata*, the *Dugong* in the *Sirenia*, the *Aye-aye* in the *Quadrupedia*, the *Diprotodon* and *Wombat* in the *Marsupialia*, and the *Narwhal* amongst the *Cetacea*, are instances of this modification; which reaches its extreme in the latter mammal in which the dentiparous force seems concentrated in a single tooth of the upper jaw, which acquires the shape of a long spiral horn.

But there is an extensive series of small *Mammalia* in which a single pair of large, curved, ever-growing incisors in each jaw is associated with so many other peculiarities of structure, as to have caused them to be regarded as a distinct order of the class, which Linnæus defined as the *Glires*, and which Cuvier called, from the habit associated with that dental modification, "*Rongeurs*," *Rodentia* or Gnawers. These incisors (fig. 87, *i*), separated by a wide interval

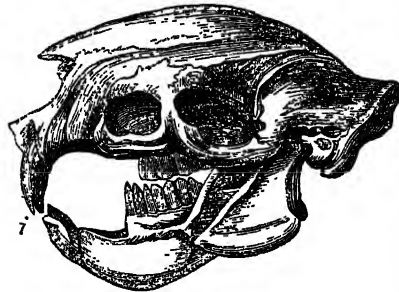

Fig. 87.

Skull and Teeth of a Porcupine.

from a short series of molars, characterize the whole order of Rodents; the single exceptional family, *Leporidae*, including Hares, Rabbits, and Picas or tailless Hares of Siberia (fig. 90) retaining a second minute incisor (*i*, 2) behind each of the large ones in the upper jaw. The incisors are regularly curved, the upper ones (fig. 88, *i*) describing a larger segment of a smaller circle, the lower ones (fig. 21) a smaller segment of a larger circle; these are the longest incisors, and usually have their alveoli extended below, or on the inner side

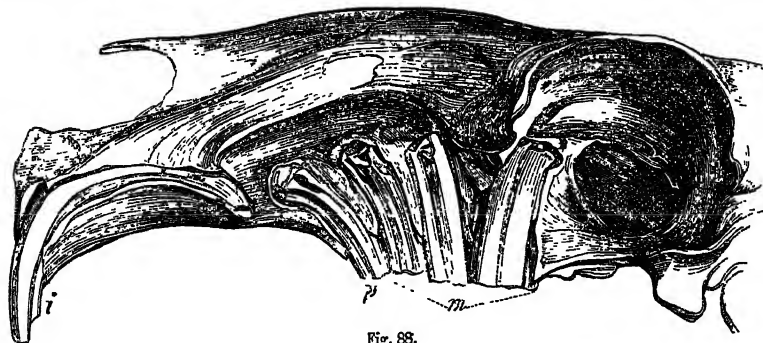

Fig. 88.

Cranium and Upper Teeth of the Patagonian Cavy (*Dolichotis*).

of those of the molars to the back part of the lower jaw (fig. 21, *i*). As in all teeth of unlimited growth, the implanted part of the incisors retains the form and size of the exposed part or crown, to the widely open base, which contains a long conical persistent dentinal pulp (fig. 21, *a*), and is surrounded by the capsule in a progressive state of ossification, as it approaches the crown, an enamel-pulp being attached to the inner side of that part of the capsule which covers the convex surface of the curved incisor. The matrix is here noticed in connection with the tooth, because it is always found in full development and activity to the time of the Rodent's death.

The calcification of the dentinal pulp, the deposition of the earthy salts in the cells of the enamel-pulp, and the ossification of the capsule, proceed contemporaneously; fresh materials being added to the base of the vascular matrix as its several constituents are progressively converted into the dental tissues in the more advanced part of the socket. The tooth, thence projecting, consists of a body of compact dentine, sometimes with a few short medullary canals continued into it from the persistent pulp-cavity, with a plate of enamel laid upon its anterior surface, and a general investment of cement, which is very thin upon the enamel, but less thin, in some Rodents, upon the posterior and lateral parts of the incisor. The substances of the incisor diminish in hardness from the front to the back part of the tooth, not only in so far as the enamel is harder than the dentine, but the enamel consists of two layers, of which the anterior and external is denser than the posterior layer, and the posterior half of the dentine is rendered by a modified number and arrangement of the dentinal tubes less dense than the anterior half.

The abrasion resulting from the reciprocal action of the upper and lower incisors produces, accordingly, an oblique surface, sloping from a sharp anterior margin formed by the dense enamel, like that which slopes from the sharp edge formed by the plate of hard steel laid on the back of a chisel; whence the name "*dentes scalprarii*," given to the incisors of the Rodentia.

The varieties to which these incisors are subject in the different Rodents are limited to their proportional size, and to the colour and sculpturing of the anterior surface. Thus in the Guinea-pig, Jerboa, and Squirrel, the breadth of the incisors is not half so great as that of the molars; whilst in the *Coyu* they are as broad, and in the Cape Mole-rats (*Bathyergus* and *Orycteromys*), broader than the molars. In the *Coyu*, Beaver, Agouti, and some other Rodents, the enamelled surface of the incisors is of a bright orange or reddish-brown colour. In some genera of Rodents, as *Orycteromys*, *Otomys*, *Meriones*, *Gurilla*, *Hydrochaerus*, *Lepus*, and *Lagomys*, the anterior surface is indented by a deep longitudinal groove. This character seems not to influence the food or habits of the species; it is present in one genus and absent in another of the same natural family. In most Rodents the anterior enamelled surface of the scalpriform teeth is smooth and uniform.

The molar teeth are always few in number, obliquely implanted and obliquely abraded; the series in each side converging anteriorly in both jaws, but they present a striking contrast to the incisors in the range of their varieties, which are so numerous that they typify almost all the modifications of form and structure which are met with in the molar teeth of the omnivorous and herbivorous genera of other orders of mammalia.

In some Rodents—*e.g.*, *Cavies* (fig. 88), the molar teeth are rootless; others—*e.g.*, the *Agouti*, have short roots, tardily developed like the molars of the Horse and Elephant; others, again—*e.g.*, the Rat and the Porcupine, soon acquire roots of the ordinary proportional length.

The differences in the mode of implantation of the molar teeth relate to the differences of diet. The Rodents, which subsist on mixed food, and which betray a tendency to carnivorous habits, as, *e.g.*, the true Rats, or which subsist on the softer and more nutritious vegetable substances, such as the oily kernels of nuts, suffer less rapid abrasion of the molar teeth; a minor depth of the crown is therefore needed to perform the office of mastication during the brief period of existence allotted to these active little Mammals; and as the economy of nature is manifested in the smallest particulars as well as in her grandest operations, no more dental substance is developed after the crown is formed, than is requisite for the firm fixation of the tooth in the jaw.

Rodents that exclusively subsist on vegetable substances, especially the coarser and less nutritious kinds, as herbage, foliage, the bark and wood of trees, wear away more rapidly the grinding surface of the molar teeth; the crowns are therefore larger, and their growth continues by reproduction of the formative matrix at their base in proportion as its calcified constituents, forming the exposed working part of the tooth are worn away. So long as this reproductive force is active, the molar tooth is implanted, like the incisor, by a long undivided continuation of the crown. When the force begins to be exhausted the matrix is simplified by the suppression of the enamel-organ, and the dentinal pulp continues to be reproduced only at certain points of the base of the crown, which by their elongation constitute the fangs. The Beaver and other Rodents, in the second category of the order, according to the implantation of the molar teeth, exemplify the above condition. But in the *Capybara*, *Dolichotis* (fig. 88), and other Rodents with rootless molars, the reproduction of the grinders, like that of the incisors, appears to continue throughout the animal's existence. The rootless and perpetually growing molars are always more or less curved (fig. 88, *p, m*); they

Teeth of Mammals.

derive from this form the same advantage as the incisors, in the relief of the delicate tissues of the active vascular matrix from the effects of the pressure which would otherwise have been transmitted more directly from the grinding surface to the growing base.

The complexity of the structure of the crown of the molar teeth, and the quantity of enamel and cement interblended with the dentine, are greatest in the rootless molars of the strictly herbivorous Rodents. The crowns of the rooted molars of the omnivorous Rats and Mice are almost as simple as the tuberculate molars of the Bear or of the human subject, which they appear to typify. They are at first tuberculate. When the summits of the tubercles are worn off, the inequality of the grinding surface is for a time maintained by the deeper transverse folds of enamel, the margins of which are separated by alternate valleys of dentine and cement; but these folds, sinking only to a slight depth, are in time obliterated, and the grinding surface is reduced to a smooth field of dentine, with a simple border of enamel. Examples of various forms assumed by the inflected folds of enamel in the molars of the *Rodentia* are given in the works of the Cuviers and other naturalists.¹ These folds have a general tendency to a transverse direction across the crown of the tooth. Baron Cuvier has pointed out the concomitant modification of the shape of the joint of the lower jaw, which almost restricts it to horizontal movements to and fro, in the direction of the axis of the head, during the act of mastication. When the folds of enamel dip in vertically from the summit to a greater or less depth into the substance of the crown of the tooth, as in those molars which have roots, the configuration of the grinding surface varies with the degree of abrasion; but in the rootless molars, where the folds of enamel extend inwards from the entire length of the sides of the tooth, the characteristic configuration of the grinding surface is maintained without variation, as in the Guinea-pig, the Capybara, and the Patagonian Cavy.

The whole exterior of the molar teeth of the *Rodentia* is covered by cement, and the external interspaces of the enamel-folds are filled with the same substance. In the *Chinchillidae* and the Capybara, where the folds of enamel extend quite across the body of the tooth, and insulate as many plates of dentine, these detached portions are held together by the cement. Such folds of enamel are usually parallel, as in the large posterior lower molar of the Capybara, which, in shape and structure, offers a very close and interesting resemblance to the molars of the Asiatic Elephant.

The modification observed in the Voles (*Arvicola*) calls to mind the molars of the African Elephant and some mastodons. The partial folds and islands of enamel in the molars of the Porcupine and Agouti typify the structure of the teeth of the Rhinoceros. The

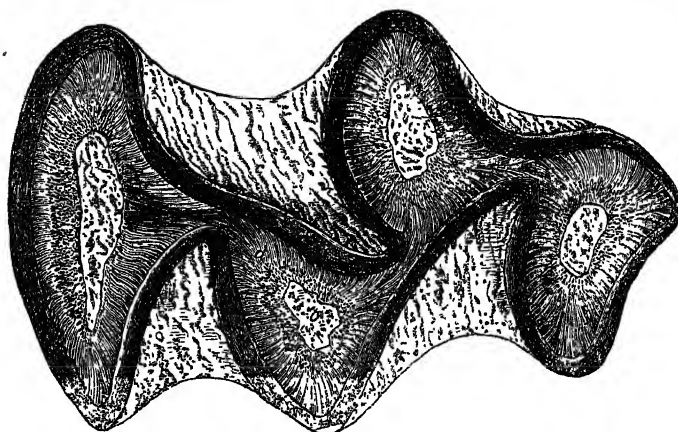

Fig. 89.

Structure of the Molar of the Water-Vole (*Arvicola amphibie*), magnified.

opposite lateral inflections of enamel in the molars of the Gerbille and Cape Mole-rat, represent the structure of the molars of the Hippopotamus. The double crescentic folds in the Jerboa sketch out, as it were, the characteristic structure of the molars of the Anoplothere and Ruminants, &c.

The transverse section of the molar of the Water-vole (fig. 89) shows that modification of the grinding surface in which the folds of enamel (*e*) extend like promontories, some outwards, the others inwards, into the substance of the crown; a like section of the Beaver's molar exhibits islands with a promontory of enamel. The transverse section of the crown of the molar of *Lagostomus* displays not fewer than five islands of enamel, which hard substance is so thick that it enters more abundantly into the composition of the tooth than the dentine itself.

The pulp, after the formation of a certain thickness of tubular dentine, becomes converted into osteo-dentine in both the rooted and rootless molars of the Rodents. This fourth substance is exhibited at *o* in the magnified transverse section of the Water-vole's molar (fig. 89), which shows the four different dental tissues, viz. cement (*c*), enamel (*e*), dentine (*d*), and osteo-dentine (*o*), entering in more equal proportions into the formation of the crown than has hitherto been demonstrated in any other mammalian tooth. When the crown is worn by mastication down to the place of the section figured, the four substances appear in the same proportions on the grinding surface, contributing to its efficiency as a triturating organ by the inequalities consequent on their various degrees of density and resistance to the abrading forces.

The molars are not numerous in any Rodent; the Hare and Rabbit (*Lepus*), have $\frac{3}{2}:\frac{3}{2}$, i. e., six molars on each side of the upper jaw (fig. 90), and five on each side of the lower jaw (fig. 91). The Pika (*Lagomys*), has $\frac{3}{2}:\frac{3}{2}$. The Squirrels have $\frac{3}{2}:\frac{3}{2}$. The families of the Dormice, the Porcupines, the Spring-rats (*Echimyidae*), the Octodonts, the Chinchillas, and the Cavies (fig. 88), have $\frac{4}{2}:\frac{4}{2}$ molars. In the great family of Rats (*Muridae*), the normal number of molars is $\frac{3}{2}:\frac{3}{2}$; but the Australian Water-rat (*Hydromys*), has but $\frac{2}{2}:\frac{2}{2}$ molars, making, with the incisors, twelve teeth, which is the smallest number in the Rodent order. The greatest number of teeth in the present order is twenty-eight, which is exemplified in the Hare and Rabbit; but forty teeth are developed in these species, ten molars and two incisors being deciduous.

In all the Rodents in which the number of molars exceeds three in a series, the additional ones are anterior to them, and are premolars, i. e., they have each displaced a deciduous predecessor in the vertical direction. This it is which constitutes the essential distinction between the dentition of the marsupial and the placental Rodent; the latter, like the placental *Carnivora*, *Quadrumania*, and *Ungulata*, having never more than three true molars. Thus the Rodents which have the molar formula of $\frac{4}{2}:\frac{4}{2}$, shed the first tooth in each series, and this is succeeded by a permanent premolar which

comes into place later than the true molars—later at least than the first and second, even when the deciduous molar is shed before birth, as was observed by Cuvier in the Guinea Pig. In the Hare and Rabbit, three anterior teeth in the upper jaw (fig. 90 *p*) succeed and displace three deciduous predecessors (fig. 90, *d*), coming into place after the first and second true molars (fig. 90, *m*) are in use, and contemporaneously with the last molar. It does not appear that the scalpriform

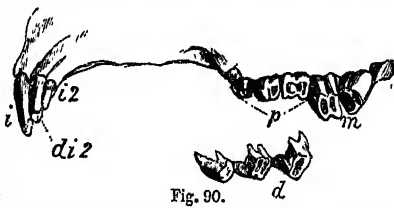

Fig. 90.

Upper Deciduous and Permanent Teeth of the Hare.

form incisors (fig. 90, *i*) are preceded by milk teeth, or, like the premolars of the Guinea Pig, by uterine teeth; but the second incisor (fig. 90, *i* 2) is so preceded—e. g., by the tooth marked *d*, *i* 2, at which period of dentition six incisors are present in the upper jaw.² This condition is interesting both as a transitory manifestation of the normal number of incisive teeth in the mammalian series, and it elucidates the disputed nature of the great anterior scalpriform teeth of the Rodentia.

Geoffroy St Hilaire contended³ that the scalpriform teeth of the Rodents were canines, because those of the upper jaw extended their fang backwards into the maxillary bone, which lodged part of

¹ See *Natural History of the Mammalia*, by G. R. Waterhouse; order Rodentia. Svo, 1849. *Ossements Fossiles*, G. Cuvier. *Les Dents de Mammifères*, F. Cuvier.

² Geoffroy St Hilaire, in his *Système Dentaire d'Oiseaux*, Svo, 1824, Appendix, p. 73, claims the discovery for himself by prevision, and for his assistant Delalande by demonstration, of this interesting fact. "Je vis là un mode d'arrangement, comme on l'avait observé chez les Kangourous; et dans la chaleur d'improvisation, je m'avais à ajouter que peut-être un cas d'atrophie avait causé l'absence de la troisième paire de dents, laquelle, ne manquant chez les lapins que pour ce motif, n'empêcherait pas qu'ils ne fussent, tout aussi bien à l'égard des incisives que sous d'autres rapports, comparables aux Kangourous. J'étais comme de coutume accompagné de M. Delalande, qui préparait mes leçons; il prit confiance dans mon aperçu; il fit, dans un intervalle de deux jours, et sans m'en parler, des recherches à cet égard; et, à la leçon suivante, il me surprit en me présentant devant les élèves plusieurs pièces fraîches: 'Voilà me dit-il, en existence positive, voici en fait, ce que vous avez présenté pouvoir être; voici les têtes des lapins avec six dents incisives.' M. Lemaire de Lisancourt, aujourd'hui membre de l'Acad. R. de Médecine, l'un de mes auditeurs à cette époque, peut se rappeler la vive sensation que cela fit sur les élèves," p. 72.

³ Isidore Geoffroy St Hilaire cites the opinion in Art. Rongeurs, Dict. Classique d'Histoire Naturelle

Teeth of
Mammals.

their hollow base and matrix. But the scalpriform teeth are confined exclusively to the premaxillary bones at the beginning of their formation, and the smaller incisors which are developed behind them, in our anomalous native Rodents, the Hare and Rabbit, retain their

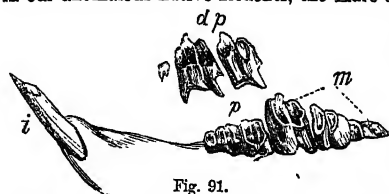

Fig. 91.

Lower Deciduous and Permanent Teeth of the Hare.

and the three molars (*m*), of the young Hare (*Lepus timidus*).

The law of the unlimited growth of the scalpriform incisors is unconditional; and constant exercise and abrasion are required to maintain the normal and serviceable form and proportions of these teeth. When, by accident, an opposing incisor is lost, or when, by the distorted union of a broken jaw, the lower incisors no longer meet the upper ones, as sometimes happens to a wounded hare,¹ the incisors continue to grow until they project like the tusks of the Elephant, and their extremities in the poor animal's painful attempts to acquire food, also become pointed like tusks. Following the curve prescribed to their growth by the form of their socket, their points often return against some part of the head, are pressed through the skin, then cause absorption of the jaw-bone, and again enter the mouth, rendering mastication impracticable, and causing death by starvation.

In the Museum of the College of Surgeons, No. 2203, Osteological Series, there is a lower jaw of a Beaver, in which the scalpriform incisor has, by unchecked growth, described a complete circle. The point has pierced the masseter muscle, and entered the back of the mouth, passing between the condyloid and coronoid processes of the lower jaw, descending to the back part of the molar teeth, in the advance of the part of its own alveolus, which contains its hollow root.

The upper jaw of a Rabbit, with an analogous abnormal growth of the scalpriform and accessory incisors, is figured in cut 92.²

Cheiromys.—In this genus of the Lemurine animals, represented by the Aye-aye (fig. 93), as in *Phascolumys* amongst the Marsupials, *Desmodus*

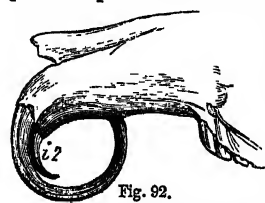

Fig. 92.

Skull and Dentition of the Aye-aye (*Cheiromys Madagascariensis*).

amongst the Bats, and *Sorex* amongst the Insectivores, the dentition is modified in analogical conformity with the Rodent type, to which, in the present instant, it makes a very close approximation, the canines being absent, and a wide vacancy separating the single pair of large-curved scalpriform incisors in each jaw from the short series of molars.

The upper incisors are compressed, presenting a narrow oval transverse section, with the long diameter from before backwards. They are curved in the segment of a circle, and deeply implanted. The short exerted crowns touch one another; their simple widely excavated fangs diverging as they penetrate the substance of the

jaw. These crowns also project obliquely forwards, and do not extend vertically downwards, as in the true *Rodentia*.

The lower incisors are more depressed, and of greater breadth from before backwards, than the upper ones. They are more curved than in the *Rodentia*, describing a semicircle, three-fourths of which are lodged in the socket, which extends backwards beyond the last molar tooth to the base of the coronoid process. The most important character by which the incisors of this anomalous Lemur differ from those of the *Rodentia* is the entire investment of enamel, which is, however, thicker upon the front than upon the back part of the tooth. The molar teeth are four on each side of the upper jaw, and three on each side of the lower jaw; implanted vertically and in parallel lines. The molars are of simple structure, with a continuous outer coat of enamel, and a flat subelliptic grinding surface. The upper ones are of unequal size, the first being the smallest and the second the largest. In the lower jaw the inequality is less, and the last molar is the least. The first and last molars above have but one root; the second and third have each three roots. The first lower molar has two roots; the second and third have each a single root. The dental formula, in the Slow Lemurs (*Stenops*), is—

$$\begin{array}{c} 22 \\ 22 \end{array}; \begin{array}{c} 11 \\ 11 \end{array}; \begin{array}{c} 33 \\ 33 \end{array}; \begin{array}{c} 33 \\ 33 \end{array} = 36.$$

In the *Stenops Tardigradus*, the first upper incisor is larger than the second, as in the genus *Tarsius*.

The true Lemurs or Makis (*Lemur, Geoff*) have the same number and kind of teeth as the Slow Lemurs.

The inferior canines are compressed and procumbent like the incisors, but are a little larger. In the upper jaw the incisors are small and vertical, with short expanded crowns; the two on the right side are separated by a wide space from the two on the left. The canine (*c*) is long, curved, compressed, sharp-edged, and pointed. The three premolars have the outer part of the crown prolonged into a compressed pointed lobe, whilst the inner part forms a tubercle, which is largest in the second and third. In the true molars the inner division of the crown is so increased as to give it a quadrate form, the outer division being divided into two pointed lobes. The first of the true molars is the largest in both jaws.

All the Quadrumana of America are distinguished from the Apes Platy- and Monkeys of the Old World by certain well-marked characters; rhynæ. of these, the position of the nostrils at the sides of the broad nose, whence their collective name, is the most conspicuous; but they have a more important dental distinction in the superior number of the premolars, which are $\frac{3}{2}$ instead of $\frac{2}{2}$, whereby the American Monkeys manifest their closer affinity to the Lemurs, and their inferior position in the zoological scale. The small "Marmosets," however, forming the genera *Hapale* and *Midas*, have but two true molar teeth on each side of both jaws—their dental formula being—

$$\begin{array}{c} 22 \\ 22 \end{array}; \begin{array}{c} 11 \\ 11 \end{array}; \begin{array}{c} 33 \\ 33 \end{array}; \begin{array}{c} 22 \\ 22 \end{array} = 32.$$

The lemurine character of the long, narrow, inferior incisors continues to be manifested by the Sakis (*Pithecia Ill.*), which, like the larger species of Platyrrhines called Howlers, Capuchins, and Spider-Monkeys, have the normal number of true molar teeth in the Quadrumanous order—their dental formula being—

$$\begin{array}{c} 22 \\ 22 \end{array}; \begin{array}{c} 11 \\ 11 \end{array}; \begin{array}{c} 33 \\ 33 \end{array}; \begin{array}{c} 33 \\ 33 \end{array} = 36.$$

The Capuchin Monkeys (*Cebus*) (fig. 94) have the four lower

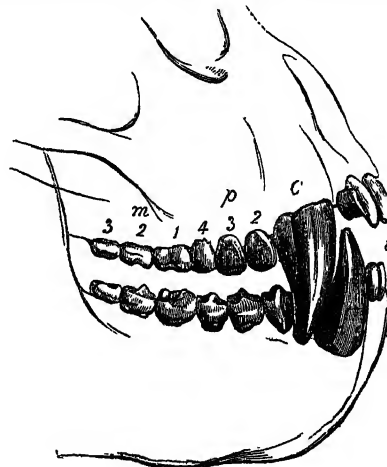

Fig. 94.

Dentition of a Capuchin Monkey (*Cebus secunulus*).

incisors (*i*) with broad, thick wedge-shaped trenchant crowns; a form

¹ Professor Budge has described and figured the upper and lower jaws of a hare with preternaturally directed and elongated tusks, in the *Verhandlungen des Naturhistor. Vereines der Treuss. Rheinlande*, 6tes Jahrgang. 8vo, 1849, p. 506.

² See the specimens, Nos. 1966-1971, *Mus. Coll. Chir.* Lond.

Teeth of
Mammals.

Teeth of Mammals.

which these teeth retain, with slight modifications, throughout the rest of the Quadrumanous order. The canines (*c*) are sufficiently developed to inflict severe wounds. The first three of the molar series (*p*, 2, 3, 4) are bicuspid premolars; the rest (*m*, 1, 2, 3) are quadricuspid true molars.

All the Platyrrhine Monkeys have four more teeth in their first dentition than the Catarrhine or Old World Quadrumanes possess—the deciduous formula being—

$$\frac{2.2}{2.2}; c \frac{1.1}{1.1}; m \frac{3.3}{3.3} = 24.$$

Fig. 95 shows the deciduous series in place, together with the first of the permanent true molars (*m*, 1); the germs of the rest of the permanent teeth are exposed in the upper jaw.

Catarrhina.

In the Catarrhine division of the order, the first or deciduous dentition consists, as in man, of—

$$\frac{2.2}{2.2}; p \frac{1.1}{1.1}; m \frac{2.2}{2.2} = 20.$$

The two milk molars are displaced and succeeded vertically by the two bicuspid premolars, and are followed horizontally by three true molars on each side of both upper and lower jaws. The permanent formula in all the Old World *Quadrumana* is—

$$\frac{2.2}{2.2}; c \frac{1.1}{1.1}; p \frac{2.2}{2.2}; m \frac{3.3}{3.3} = 32.$$

The incisors have always a shape conformable to their name, but are very thick and strong; in the upper jaw the middle are larger than the lateral ones, and both are larger than those below. The canines are conical, pointed, with trenchant posterior margins, always longer than the adjoining teeth, and acquiring, in the males of the great Baboons and Orangs, the proportions of those teeth in the true *Carnivora*. The Mandrills (*Cynocephalus maimon*) have these dental weapons most formidable for their size and shape; especially the upper pair, which descend behind the

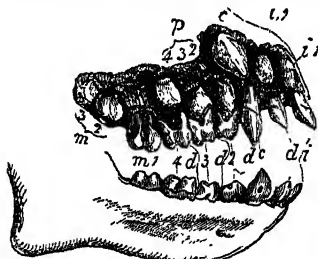

Fig. 95.

Deciduous and Permanent Teeth of a Young *Cebus apella*.

crowns of the lower incisors, and along the outside of the first lower premolars, the crowns of which seem as if bent back by the action of the upper canines; the anterior longitudinal groove of these canines is very deep, their posterior margin very sharp. A long diastema divides the upper canine from the incisors, a short one separates it from the premolars; these and the three true molars, are arranged in a straight line. In the great Orang-utan (*Pithecius Wurmii*) the median incisors of the upper jaw are of unusual size and strength; the thickness (antero-posterior diameter) of the base of the crown almost equals the breadth of the same; and they are double the size of the lateral incisors. The abraded surface of the front incisors in the old Orang forms a broad tract extending obliquely from the cutting edge to the back part of the base of the crown; the lateral incisors are more pointed, the outer angle being obliquely truncated; a vacant space of their own breadth divides them from the canines. These, in the male of the Great Orang (*Wurmii's Pongo*), have a long and strong slightly-curved crown, extending below the alveolar border of the under jaw when the mouth is shut, with a moderately sharp posterior margin, but without an anterior groove; the crown is convex externally, with a slight convexity between two longitudinal depressions on the inner surface. In the female Orang the canines are smaller; the crowns extend only a short distance beyond the level of the adjoining molars.¹

In the upper jaw both premolars and molars are implanted by three diverging roots, two external and one internal; in the lower jaw the corresponding teeth are each implanted by two strong diverging roots; the series of grinders forms a straight line on each side of both jaws.

As the precise characteristics of the human dentition are best demonstrated by comparison with that brute species which is most nearly allied to man, and makes the first step in the descending scale, the details of such a comparison may perhaps be not unacceptable, as one of its subjects is a species of Chimpanzee (*Troglodytes Gorilla*), unknown to science when the writer's "Odontography" was published, and which, so far as its organization is known, is more anthropoid than even the docile and smaller species of Chimpanzee (*Troglodytes niger*). A side view of the teeth of a male full-grown, but not aged, specimen of the great Chimpanzee is given of the natural size in (fig. 96). This dentition, though in all its prin-

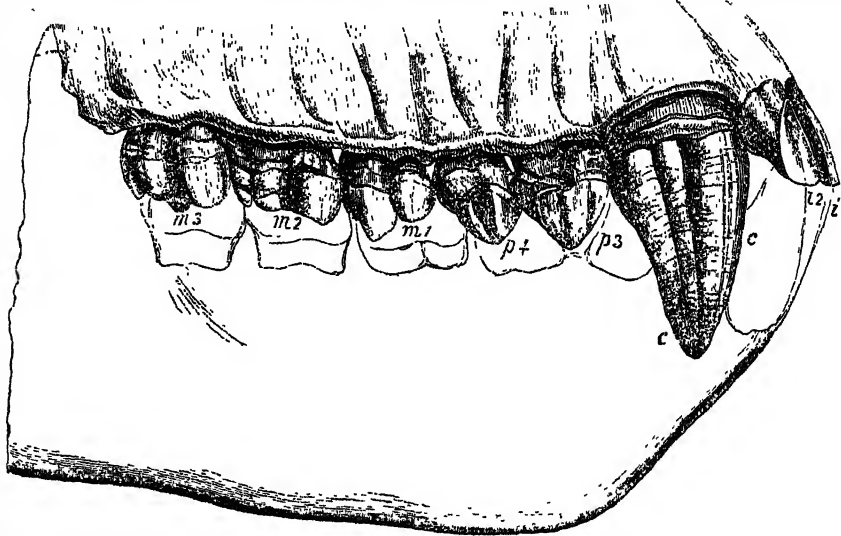

Fig. 96.

Dentition of an Adult Male (*Troglodytes Gorilla*), nat. size.

cipal characters strictly quadrumanous, yet, in the minor particulars in which it differs from the dentition of the Orang, approaches nearer the human type. In the upper jaw the middle incisors (*i*) are smaller, the lateral ones (fig. 96, *i*, 2) larger than those of the Orang; they are thus more nearly equal to each other; nevertheless the proportional superiority of the middle pair is much greater than in Man, and the proportional size of the four incisors both to the entire skull and to the other teeth is greater. Each incisor has a prominent posterior basal ridge, and the outer angle of the lateral incisors (*i*, 2) is rounded off as in the Orang. The incisors incline forwards from the vertical line as much as in the great Orang. Thus the characteristics of the human incisors are, in addition to their true incisive wedge-like form, their near equality of size, their vertical or nearly vertical position, and small relative size to the other teeth and to the entire skull. The diastema between the incisors and the canine on each side is as well marked in the male Gorilla as in the male Orang. The crown of the canine (fig. 96, *c*), passing outside the interspace between the lower canine and premolar, extends in the male *Troglodytes Gorilla* a little below the alveolar border of the under jaw when the mouth is shut; the upper canine of the male *Troglodytes niger* likewise projects a little below that border. In the male of the smaller Chimpanzee (*Troglodytes niger*), the upper canine is conical, pointed, but more compressed than in the Orang, and with a sharper posterior edge; convex anteriorly, becoming flatter at the posterior half of the outer surface, and concave on the corresponding part of the inner surface, which is traversed by a shallow longitudinal impression; a feeble longitudinal rising, and a second linear impression divide this from the convex anterior surface, which also bears a longitudinal groove at the base of the crown. The canine is rather more than twice the size of that in the female. In the male *Gorilla* (fig. 96, *c*), the crown of the canine is more inclined outwards; the anterior groove on the inner surface of the crown is deeper; the posterior groove is continued lower down upon the fang, and the ridge between the two grooves is more prominent than in the *Troglodytes niger*. Both premolars (fig. 96, *p* 3 and *p* 4) are bicuspid; the outer cusp of the first, and the inner cusp of the second being the largest, and the first premolar (*p* 3) consequently appearing the largest on an external view. The difference is well marked in the

¹ In the writer's *Odontography* (1842, p. 442) is recorded a variety which he observed in the dentition of a full-grown Orang-utan, in the collection of the Baron Van der Capella at Utrecht, viz., a supernumerary molar on each side of both jaws, making six molars, of which two only had the form of premolars.

In the Calcutta museum Mr Blyth has noticed in an adult female Bornean Orang, a fourth true molar on the left side of both upper and lower jaw, the supernumerary tooth above being of a round shape, and very small.

In a collection of skulls of the smaller species of Orang recently sent from Borneo (*Pithecius Morio*), the writer observed the skull of an adult male with the same supernumerary molar on each side of the upper jaw, but not in the lower jaw.—*Trans. Zool. Soc.*

These instances illustrate the tendency to variety in the remarkable Anthropoid Apes of Borneo, a tendency which seems to be also manifested in an occasional arrest of development of the characteristic long upper extremities.

Teeth of
Mammals.

female (fig. 97). The anterior external angle of the first premolar is not produced as in the Orang, which in this respect makes a marked approach to the lower *Quadrumania*. In Man, where the outer curve

is three times the size of the human first premolar (*p* 3); it has a sub-triangular crown, with the anterior and outer angle produced forwards, slightly indicating the peculiar feature of the same tooth in the

Mammals.

Fig. 97.

Dentition of an Adult Female Gorilla.

of the premolar part of the dental series is greater than the inner one, the outer cusps of both premolars are the largest; the alternating superiority of size in the Chimpanzee accords with the straight line which the canine and premolars form with the true molars.

The true molars (fig. 96, *m* 1, *m* 2, *m* 3) are quadricuspid, relatively larger in comparison with the bicuspid than in the Orang. In the first and second molars of both species of Chimpanzee, a low ridge connects the antero-internal with the postero-external cusp, crossing the crown obliquely, as in Man. There is a feeble indication of the same ridge in the unworn molars of the Orang; but the four principal cusps are much less distinct, and the whole grinding surface is flatter and more wrinkled than in the Chimpanzee. In the *Troglodytes niger* the last molar is the smallest, owing to the inferior development of the two hinder cusps, and the oblique connecting ridge is feebly marked. In the *Troglodytes Gorilla* this ridge is as well developed as in the other molars, but is more transverse in position; and the crown of *m* 3 is equal in size to that of *m* 1 or *m* 2, having the posterior outer cusp, and particularly the posterior inner cusp, more distinctly developed than in the *Troglodytes niger*. The repetition of the strong sigmoid curves which the unworn prominences of the first and second true molars present in Man, is a very significant indication of the near affinity of the Chimpanzee as compared with the approach made by the Orangs or any of the inferior *Quadrumania*, in which the four cusps of the true molars rise distinct and independently of each other. A low ridge girds the base of the antero-internal cusp of each of the upper true molars in the male Chimpanzee; it is less marked in the female. The premolars as well as molars are severally implanted by one internal and two external fangs, diverging but curving towards each other at their ends, as if grasping the substance of the jaw. I have found the two outer fangs of the second premolar connate in one female specimen of the *Troglodytes niger*. In no variety of the human species are the premolars normally implanted by three fangs; at most the root is bifid, and the outer and inner divisions of the root are commonly connate. It is only in the black varieties, and more particularly that race inhabiting Australia, that I have found the wisdom tooth (*m* 3) with three fangs as a general rule; and the two outer ones are more or less confluent.

In the lower jaw of the Gorilla the lateral incisors are broader than the middle ones, although they are smaller relatively than in the *Troglodytes niger*; they are larger and less vertically implanted than in Man. The lower canines are two inches and a half in length, including the root; the enamelled crown is an inch and a quarter in length, and nearly an inch across the base; it is conical and trihedral; the outer and anterior surface is convex, the other two surfaces are flattened or subconcave, and converging to an almost trenchant edge directed inwards and backwards; a ridge separates the convex from the antero-internal flat surface; both this and the posterior surface show slight traces of a longitudinal rising at their middle part. The lower canine of the male shows the same relative superiority of size as the upper one compared with that in the female in both species of Chimpanzee. The canine almost touches the incisor, but is separated by a diastema one line and a half broad from the first premolar. This tooth (*p* 3) is larger externally than the second premolar, and

The three true molars are equal in size in the *Troglodytes Gorilla*; in the *Troglodytes niger* (fig. 98), the first (*m* 1) is a little larger than the last (*m* 3), which is the only molar in the smaller Chimpanzee as large as the corresponding tooth in the black varieties of the human subject, in most of which, especially the Australians (fig. 99), the true molars attain larger dimensions than in the yellow or white races. The four principal cusps, especially the two inner ones of the first molar of both species of Chimpanzee, are more pointed and prolonged than in Man; a fifth small cusp is developed behind the outer pair, as in the Orangs and the Gibbons, but is less than that in Man. The same additional cusp is present in the second molar, which is seldom seen in Man. The crucial groove on the grinding surface is much less distinct than in Man, not being continued across the ridge connecting

the anterior pair of cusps in the Chimpanzee. The crown of the third molar is longer antero-posteriorly from the greater development of the fifth posterior cusp, which, however, is rudi-

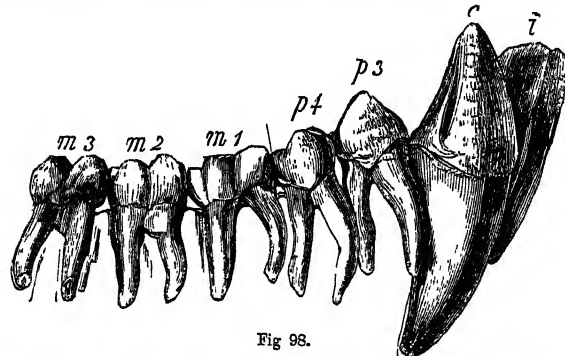

Fig. 98.

Teeth of Right Side, Lower Jaw, of adult male Chimpanzee, (*Troglodytes niger*). Nat. size.

mental in comparison with that in the Semnopithecus and Macaques. All the three true molars are supported by two distinct and well-developed antero-posteriorly compressed divergent fangs, longitudinally excavated on the sides turned towards each other; in the white and yellow races of the human subject these fangs are usually connate in *m* 3, and sometimes also in *m* 2. The molar series in both species of Chimpanzee forms a straight line, with a slight tendency, in the upper jaw, to bend in the opposite direction to the well-marked curve which the same series describes in the human subject.

This difference of arrangement, with the more complex implantation of the premolars, the proportionally larger size of the incisors as compared with the molars; the still greater relative magnitude of the canines; and, above all, the sexual distinction in that respect illustrated by figs. 96 and 97, stamp the Gorillas and Chimpanzees most decisively with not merely specific but generic distinctive characters as compared with Man. For the teeth are fashioned in their shape and proportions in the dark recesses of their closed formative alveoli, and do not come into the sphere of operation of external modifying causes until the full size of the crowns has been acquired. The formidable natural weapons with which the Creator has armed the powerful males of both species of Chimpanzee, form the compensation for the want of that psychological capacity to forge destructive instruments which has been reserved, as his exclusive prerogative, for Man. Both Chimpanzees and Orangs differ from the human subject in the order of the development of the permanent series of teeth; the second molar (*m* 2) comes into place before either of the premolars has cut the gum, and the last molar (*m* 3) is acquired before the canine. We may well suppose that the larger grinders are earlier required by the frugivorous Chimpanzees and Orangs than by the higher organized omnivorous species with more numerous and

Teeth of Mammals.

Homo.

varied resources, and probably one main condition of the earlier development of the canines and premolars in Man may be their smaller relative size.

Having reached, in the Gorilla, the highest step in the series of the brute creation, our succeeding survey of the human dental system, cleared and expanded by retrospective comparison, becomes fraught with peculiar interest, since every difference so detected establishes the true and essential characteristics of that part of man's frame.

The human teeth are the same in number and in kind as those of the Chimpanzee and Orang-utan, nor does man differ in this respect from any of the inferior catarrhine Quadrumanes. The human dental formula is therefore—

$$\frac{2.2}{2.2}; \frac{1.1}{1.1}; \frac{2.2}{2.2}; \frac{3.3}{3.3} = 32;$$

that is to say, there are on each side of the jaw, both above and below, two incisors, one canine, two premolars, and three true molars.

They are more equal in size than in the *Quadrumana*. No tooth surpasses another in the depth of its crown; and the entire series, which describes in both jaws a regular parabolic curve, is uninterrupted by any vacant space (fig. 99). The most marked distinction

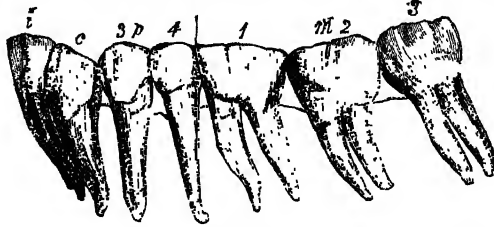

Fig. 99.

Teeth of Left Side, Lower Jaw, of Adult Male Australian. Nat. size.

between the dentition of Man and that of the highest Quadrumanes, is the absence of the interval between the upper lateral incisor and the canine, and the comparatively small size of the latter tooth (fig. 100, c); but its true character is indicated by the conical form of the crown, which terminates in an obtuse point, is convex outwards, and flat or sub-concave within, at the base of which surface there is a feeble prominence. The conical form is best expressed in the Melanian races, especially the Australian (fig. 99, c). The canine is more deeply implanted, and by a stronger fang than the incisors; but the contrast with the Chimpanzee is sufficiently manifest, as is shown in fig. 98. There is no sexual superiority of size either of the canine or any other single tooth in the human subject.

Both upper and lower premolars (fig. 99, p 3 and 4) are bicuspid; they are smaller in proportion to the true molars than in the Chimpanzee and Orang. In the upper premolars a deep straight fissure at the middle of the crown divides the outer and larger from the inner and smaller cusp; in the lower premolars the boundary groove describes a curve concave towards the outer cusp, and is sometimes obliterated in the middle by the extension of a ridge from the outer to the inner cusp, which cusp is smaller in proportion than in the upper premolars. These teeth in both jaws are apparently implanted each by a single, long, subcompressed, conical fang; but that of the upper premolars is shown by the bifurcated pulp-cavity to be essentially two fangs, connate, and which, in some instances, are separated at their extremities.

The crowns of the true molars (fig. 99, m 1, 2, 3) are larger in proportion to the jaws, are a little larger in proportion to the bicuspid, and still more so in proportion to the canine and incisor teeth, than in the Chimpanzees and Orangs. The contour of the grinding surface is more rounded, and we have seen that the higher *Quadrumana* already approximate to this character by the angles of the crown being less marked than in the lower *Quadrumana*. The first and second true molars of the upper jaw support four trihedral cusps; the internal and anterior one is the largest, and is connected with the external and posterior cusp by a low ridge extending obliquely across the grinding surface, with a deep depression on each side of it; the anterior groove extending to the middle of the outer surface, the posterior one to the inner surface. The enamel is first worn away by mastication from the anterior and internal or largest tubercle, a line of enamel extending from the outside to the middle of the crown is the last to be removed before the grinding surface is reduced to a field of dentine with a simple ring of enamel. It is worthy of remark, that by the time when the permanent teeth have come into place the first true molar in both jaws is much more worn, as compared with the second and third molars, than it is in the Chimpanzee or Orang, owing to the slow attainment of maturity characteristic of the human species, and the longer interval which elapses between the acquisition of the first and the last true molars, than in the highest *Quadrumana*. In the last true molar, called from its late appearance the "dens sapientiae," or wisdom-tooth, the two inner tubercles are blended together, and a fissure extends in many instances, especially in the Melanian varieties, from the middle of the grinding surface, at right angles to that dividing the two outer cusps, to the posterior border of the tooth.

Teeth of Mammals.

The first upper molar is always implanted by three diverging fangs, two external and one internal. The second molar is usually similarly implanted, but the two outer fangs are less divergent, are sometimes parallel, and occasionally connate; this variety appears to be more common in the Caucasian than in the Melanian races; and in the Australian skulls examined by the writer, the wisdom-tooth has always presented the same three-fanged implantation as in the Chimpanzee and Orang.

The crowns of the inferior true molars are quinque-cuspid, the fifth cusp being posterior and connected with the second outer cusp; it is occasionally obsolete in the second molar. The four normal cusps are defined by a crucial impression, the posterior branch of which bifurcates to include the fifth cusp; this bifurcation being most marked in the last molar where the fifth cusp is most developed. In the first molar a fold of enamel, extending from the inner surface to the middle of the crown, is the last to disappear from the grinding surface in the course of abrasion. The wisdom-tooth (fig. 99, m 3) is the smallest of the three molars in both jaws, but the difference is less in the Melanian than in the Caucasian races. Each of the three lower molars is inserted by two sub-compressed fangs, grooved along the side, turned towards each other. This double implantation appears to be constant in the Melanian, especially the Australian race (fig. 99), in which the true molars are relatively larger than those of the Caucasian race. In Europeans it is not unusual to find the two fangs in both the second and third molars connate along a great part or the whole of their extent.

With respect to the reciprocal apposition of the teeth of the upper and lower jaw, it is interesting to observe that the crown of the lower canine is, as usual, in advance of that above, and fits into the shallow notch between that and the lateral incisor. The inferior incisors are so small that their anterior surface rests against the posterior surface of the upper ones when the mouth is closed; the other teeth are opposed crown to crown, the upper teeth extending a little more outwardly than the lower ones.

Hunter remarks that the supernumerary teeth happen oftener in the upper than in the under jaw, and he believed them to be always incisors or canines. In the Osteological series of the Museum of the London College of Surgeons there is a skull of a male Hindoo (No. 5541), in which there were two well-formed canine teeth placed side by side in the left upper jaw, the series being very regular and even. The wisdom-tooth is sometimes not developed.

The deciduous series of teeth in the human subject (fig. 100) consists of—

$$\frac{2.2}{2.2}; \frac{1.1}{1.1}; \frac{2.2}{2.2} = 20.$$

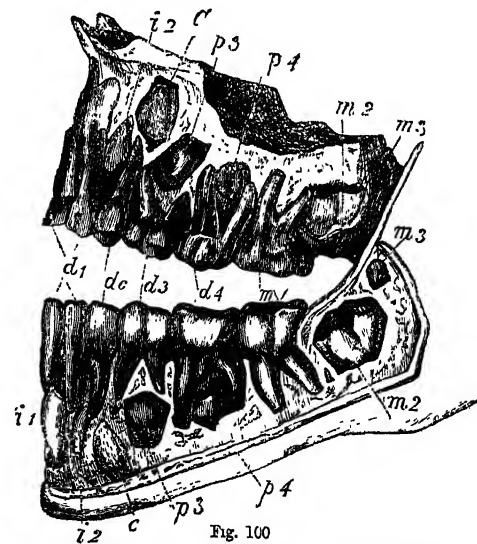

Fig. 100

Deciduous and Permanent Teeth, Human Child: et. 6½.

The upper milk incisors of the Chimpanzee are relatively larger than in Man, especially the middle pair; but the disproportionate size of these is still more manifest and characteristic of the Orang. The crown of the canine is longer and more pointed in the Chimpanzee than in Man; still more so, and further apart from the incisor in the Orang. The first upper milk-molar (fig. 100, d 3) is as large in the human subject as in the Chimpanzee, and its crown is divided into two principal cusps, but the outer and larger one has a small subdivision notched off posteriorly, and the inner cusp is relatively larger than in the Chimpanzee. The first upper milk-molar of the Orang is simply bicuspid, but is larger than in the Chimpanzee. The second milk-molar of the human child (fig. 100, d 4) could scarcely be distinguished from that of the young Chimpanzee; both are quadricuspid, and the same oblique ridge crosses the grinding surface from the antero-internal to the postero-external

Teeth of Mammals.

tubercle; but the pointed summits of the two outer cusps are a little more produced in the Chimpanzee. The second molar of the Orang, besides its larger size, has the four tubercles better defined, and the oblique ridge less developed. The lower deciduous incisors of the anthropoid Apes differ from those of the human subject in their superior size, greater relative thickness, and, in the lateral incisor more particularly, by the rounding off of the outer angle. The lower canine of the Chimpanzee has a longer, larger, and more pointed crown, with a sharp posterior edge; it is less marked in the canine of the Orang, which is larger and thicker than in the Chimpanzee. The crowns of the upper and lower canines are more obliquely opposed, the lower one being more advanced in those apes than in the human subject. The first lower deciduous molar of the human subject has four tubercles and a small anterior ridge, and is larger than that of the Chimpanzee, which supports a single large-pointed cusp, and a posterior ridge. The corresponding molar of the Orang has a similar simple crown, but is as large as that of the human child. The second lower milk molar (fig. 100, *d* 4) is of equal or superior size in the human subject to that in the Chimpanzee, but it supports three outer and two inner cusps, while in the Chimpanzee it has but four cusps. In the Orang the fifth external and posterior tubercle is feebly indicated. The deciduous molars of the human subject, as in the Chimpanzee and Orang, have each three fangs in the upper, and two in the lower jaw.

The differences brought out by the foregoing comparisons, though less striking than those exhibited by the permanent teeth, will be appreciated by the philosophical anatomist as yielding more certain evidence of the essential distinction of the Bimanous species. He will perceive that they are not due to mere adaptive developments, but are manifested at a period when the subjects of comparison are far from having attained the pre-ordained term of deviation from the common type; that they are antecedent to those changes in the dental system itself, which more broadly characterize the species, and, in the Orang and Chimpanzee, proceed further to differentiate the male and female sexes.

Homo. Develop- ment.

Calcification of the permanent series of teeth commences first in the pulp of the first true molar (fig. 100, *m* 1), and, very soon after, if not simultaneously, in that of the anterior incisor (*i* 1), about five or six months after birth. The first true molar (*m* 1) comes into place and use between the sixth and seventh year; the first permanent incisor (*i* 1) between six years and a half and eight years; the calcification of the pulps of the lateral incisor (*i* 2) and canine (*c*) commences about eight or nine months after birth, and they cut the gum, the canine quickly following the incisor, between the seventh and ninth years. Calcification of the first premolar (*p* 3) begins at, or soon after, the second year; that of the second about a year later; and both premolars (*p* 3 and 4) have displaced the deciduous molars (*d* 3 and 4), and come into use between the eighth and tenth years. The pulp of the second molar (*m* 2) begins to be calcified about the fifth or sixth year, and it cuts the gum from about the twelfth year to the fourteenth year, but always later than the permanent canines and premolars. The third molar (*m* 3) begins to be calcified about the twelfth year, and usually comes into place at or after the twentieth year.

Both earlier and later periods of the development of the permanent teeth have been observed and recorded; but such varieties rarely affect the general order of succession. This order is here described as it occurs in the lower jaw, the teeth of which usually appear earlier than the corresponding ones above. It will be seen, therefore, that the human subject differs from the Chimpanzee and Orang in the order of progression of the permanent teeth.

John Hunter, after indicating the first incisor and the first molar as the earliest of the adult teeth that are formed, rightly observes, "The teeth between these two points make a quicker progress than those behind."¹ In the *Quadruman* the progress is slower, the second molar preceding in the order of development the bicuspid, and the last molar the canines.

The Lion (*Felis Leo*) may be taken as the type of the flesh-feeders. The largest and most conspicuous teeth in this and the other feline quadrupeds are the canines (fig. 101, *c*); they are of great strength, deeply implanted in the jaw, with the fangs thicker and longer than the enamelled crown; this part is conical, slightly recurved, sharp-pointed, convex in front, with one or two longitudinal grooves on the outer side, almost flat on the inner side, and with a sharp edge

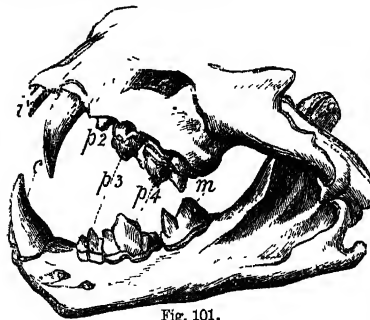

Fig. 101.

Dentition of the Lion.

the outer side, almost flat on the inner side, and with a sharp edge

behind. The lower canines pass in front of the upper ones when the mouth is closed.

The incisors, six in number on both jaws, form a transverse row; the outermost above (fig. 101, *i*) is the longest, resembling a small canine; the intermediate ones have broad and thick crowns indented by a transverse cleft. The first upper premolar (*p* 2) is rudimentary; there is no answerable tooth in the lower jaw. The second (*p* 3), in both jaws, has a strong conical crown supported on two fangs. The third upper tooth (*p* 4) has a cutting or trenchant crown divided into three lobes, the last being the largest, and with a flat inner side, against which the cutting tooth (*m*) in the lower jaw works obliquely. Behind, and on the inner side of the upper tooth (*p* 4), there is a small tubercular tooth. The feline dental formula is—

$$\begin{matrix} i & 3.3 & ; & c & 1.1 & ; & p & 3.3 & ; & m & 1.1 \\ 3.3 & & & 1.1 & & & 2.2 & & & 1.1 \end{matrix} = 30.$$

A glance at the long sub-compressed, trenchant, and sharp-pointed canines, suffices to appreciate their peculiar adaptation to seize, to hold, to pierce, and lacerate a struggling prey. The jaws are strong, but shorter than in other carnivora, and with a concomitant reduction in the number of teeth; thus the canines are brought nearer to the insertion of the very powerful biting muscles, called "temporal" and "masseter," which work them with proportionally greater force. The use of the small pincer-shaped incisor teeth is to gnaw the soft, grisly ends of the bones, and to tear and scrape off the tendinous attachments of the muscles and periosteum. The compressed trenchant blades of the sectorial teeth play vertically upon each other's sides like the blades of scissors, serving to cut and coarsely divide the flesh; and the form of the joint of the lower jaw almost restricts its movement to the vertical direction, up and down. The wide and deep zygomatic arches, and the high crests of bone upon the skull concur in completing the carnivorous physiognomy of this most formidable existing species of the feline tribe.

The penultimate tooth in the upper jaw (fig. 101, *p* 4), and the last tooth in the lower jaw (fig. 101, *m*), were denominated by Cuvier "dents carnassières," which has been rendered "dens sectorius," the "sectorial," or scissor-tooth.² It is a very characteristic tooth in the carnivorous order, but undergoes many modifications, and preserves its typical form, as represented in figures 102 and 103, only in the most strictly flesh-feeding species. In it may be distinguished the part called the "blade" (fig. 102,

Fig. 102.

Working Surface of the Upper Sectorial Tooth, Hyæna. Nat. size.

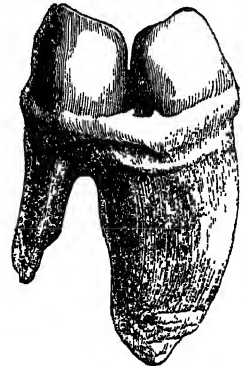

Fig. 103.

Side view of Lower Sectorial Tooth, Lion. Nat. size.

b, *b*), and the part called the "tubercle" (fig. 102, *t*). The lower sectorial in the genus *Felis* consists exclusively of the blade (fig. 103), which is pretty equally divided into two lobes. The blade of the upper sectorial always plays upon the outside, and a little in advance of the lower sectorial.

The upper permanent sectorial (fig. 104, *p* 4) succeeds and displaces a deciduous tubercular molar (fig. 104, *d* 4) in all carnivora, and is, therefore, essentially a premolar tooth; the lower sectorial (fig. 104, *m* 1) comes up behind the deciduous series (*d* 3, *d* 4) and has no immediate predecessor; it is, therefore, a true molar, and the first of that class. By these criteria the sectorial teeth may always be distinguished under every transitional variety of form which they present in the carnivorous series, from *Machairodus* (fig. 145, VI.), in which the crown consists exclusively of the "blade" in both jaws, to *Ursus* (fig. 109), in which it is totally tubercular; the development of the tubercle bearing an inverse relation to the carnivorous propensities of the species.

The dentition of this genus presents a nearer approach to the strictly carnivorous type, than in other *Carnivora*, by the reduction of the tubercular molars to a single minute tooth on each side of the upper jaw, the inferior molars being all conical or sectorial teeth; the molar teeth in both jaws are larger and stronger, and the canines smaller in proportion than in the Feline species, from the formula of which the dentition of the hyæna differs numerically only in the retention of an additional premolar tooth, *p* 1 above and *p* 2 below, on each side of both jaws. The dental formula of the genus *Hyæna* is:—

$$\begin{matrix} i & 3.3 & ; & c & 1.1 & ; & p & 4.4 & ; & m & 1.1 \\ 3.3 & & & 1.1 & & & 3.3 & & & 1.1 \end{matrix} = 34.$$

² Odontography, p. 475.

Order Carnivora Felis.

Teeth of Mammals.

Teeth of
Mammals

The crowns of the incisors form almost a straight transverse line in both jaws, the exterior ones, above, being much larger than the four middle ones, and extending their long and thick inserted base further

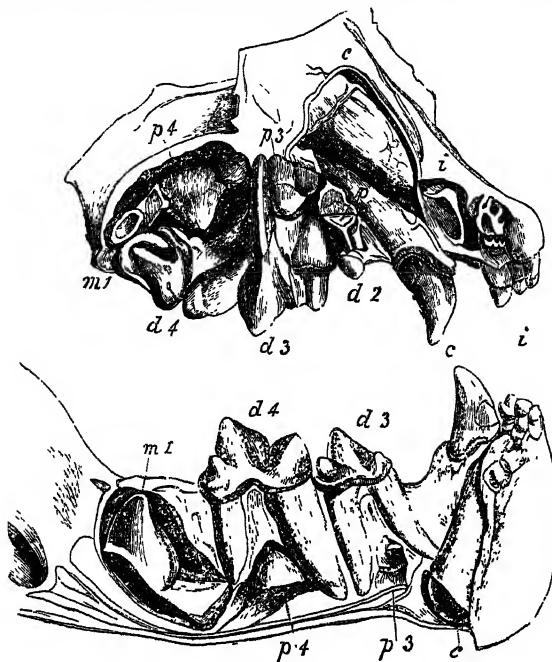

Teeth of
Mammals.

Fig. 104.
Deciduous Teeth; young Lion.

back; the crown of the upper and outer incisor is strong, conical, recurved, like that of a small canine. The four intermediate small incisors have their crown divided by a transverse cleft into a strong anterior, conical lobe, and a posterior ridge, which is notched vertically; giving the crown the figure of a trefoil. The lower incisors gradually increase in size from the first to the third; this and the second have the crown indented externally; but they have not the posterior notched ridge like the small upper incisors; the apex of their conical crown fits into the interspace of the three lobes of the incisor above. The canines have a smooth convex exterior surface, divided by an anterior and posterior edge from a less convex inner side; this surface is almost flat and of less relative extent in the inferior canines. The first premolar above (*p* 1) is very small, with a low, thick, conical crown; the second presents a sudden increase of size, and an addition of a posterior and internal basal ridge to the strong cone. The third premolar exhibits the same form on a still larger scale, and is remarkable for its great strength. The posterior part of the cone of each of these premolars is traversed by a longitudinal ridge. The fourth premolar above is the carnassial tooth (fig. 102), and has its long blade (*b*, *b*) divided by two notches into three lobes, the first a small thick cone, the second a long and compressed cone, the third a horizontal sinuous trenchant plate; a strong triedral tubercle (*t*) is developed from the inner side of the base of the anterior part of the crown. The single true molar of the upper jaw is a tubercular tooth of small size. The first premolar of the lower jaw, (fig. 105, *p* 2) fits into the interspace between the first and second premolars above, and answers, therefore, to the second lower premolar

Fig. 105.

Dentition, Lower Jaw, of the Hyæna.

ably less in the *Hyæna crocuta* than in the *H. vulgaris*; its posterior ridge is developed into a small cone; the last tooth (*m* 1) is the sectorial,

and consists almost entirely of a blade divided by a vertical fissure into two sub-equal compressed pointed lobes; the points are less produced than in the Felines, but the lower sectorial of the hyæna is better distinguished by the small posterior basal talon, from which a ridge is continued along the inner side of the base, and is slightly thickened at the forepart of the crown.

The deciduous teeth consist of—

$$\begin{matrix} i & 3.3 \\ 3.3 \end{matrix}; \begin{matrix} c & 1.1 \\ 1.1 \end{matrix}; \begin{matrix} m & 3.3 \\ 3.3 \end{matrix} = 22.$$

The first normal deciduous molar is two-fanged, and has a more compressed and consequently more carnassial crown than that of the second permanent premolar, by which it is succeeded. The second deciduous molar is the sectorial tooth; the inner tubercle is continued from the base of the middle lobe, and thus resembles the permanent sectorial of the Glutton (*Gulo*) and many other *Mustelidae*; the deciduous tubercular molar is relatively larger than in the adult *Hyæna*, and offers another feature of resemblance to the permanent dentition of the Glutton. It is also worthy of remark that the exterior incisor of the upper jaw is not only absolutely, but relatively smaller in the immature than in the adult dentition of the hyæna, and again illustrates the resemblance to the more common type of dentition in the Carnivora.

The permanent dentition of the *Hyæna*, as of other genera or families of the Carnivora, assumes those characteristics which adapt it for the peculiar food and habits of the adult, and mark the deviation from the common type, which always accompanies the progress to maturity. The most characteristic modification of this dentition is the great size and strength of the molars as compared with the canines, and more especially the thick and strong conical crowns of the second and third premolars in both jaws, the base of the cone being belted by a strong ridge which defends the subjacent gum.¹ This form of tooth is especially adapted for gnawing and breaking bones, and the whole cranium has its shape modified by the enormous development of the muscles which work the jaws and teeth in this operation.² Adapted to obtain its food from the coarser parts of animals which are left by the nobler beasts of prey, the hyæna chiefly seeks the dead carcass, and bears the same relation to the lion which the vulture does to the eagle. In consequence of the quantity of bones which enter into its food, the excrements consist of solid balls of a yellowish white colour, and of a compact earthy fracture. Such specimens of the substance, known in the old *Materia Medica* by the name of "album græcum," were discovered by Dr Buckland in the celebrated ossiferous cavern at Kirkdale. They were recognised at first sight by the keeper of a menagerie, to whom they were shown, as resembling both in form and appearance the faeces of the spotted Hyæna; and, being analysed by Dr Wollaston, were found to be composed of the ingredients that might be expected in faecal matter derived from bones, viz. phosphate of lime, carbonate of lime, and a very small proportion of the triple phosphate of ammonia and magnesia. This discovery of the coprolites of the hyæna formed, perhaps, the strongest of the links in that chain of evidence by which Dr Buckland proved that the cave at Kirkdale, in Yorkshire, had been, during a long succession of years, inhabited as a den by hyænas, and that they dragged into its recesses the other animal bodies, whose remains, splintered and bearing marks of the teeth of the hyæna, were found mixed indiscriminately with their own.

This family of *Carnivora*, which comprehends the Civets, Genets, Viverridae, Ichneumons, Musangs, Surikates, and Mangles, is characterized with few exceptions, by the following formula:—

$$\begin{matrix} i & 3.3 \\ 3.3 \end{matrix}; \begin{matrix} c & 1.1 \\ 1.1 \end{matrix}; \begin{matrix} p & 4.4 \\ 4.4 \end{matrix}; \begin{matrix} m & 2.2 \\ 2.2 \end{matrix} = 40,$$

(fig. 106). It differs from that of the genus *Canis* by the absence of a tubercular tooth

Fig. 106.

Dentition of Cynogale.

and more tubercular character of the sectorial teeth.

The canines are more feeble, and their crowns are almost smooth; the premolars, however, assume a formidable size and shape in some aquatic species, as those of the sub-genus *Cynogale* (fig. 106), in which their crowns (*p* 1-4) are large, compressed, triangular, sharp-pointed, with trenchant and serrated edges, like the teeth of certain sharks, (whence the name *Squalodon*, proposed for one of the species), and well adapted to the exigencies of quadrupeds subsisting principally on fish; the opposite or obtuse, thick form of the premolars is manifested by some of the Musangs, as *Paradoxurus auratus*.

¹ An eminent civil engineer, to whom the writer showed the jaw of a hyæna, observed that the strong conical tooth, with its basal ridge, was a perfect model of a hammer for breaking stones for roads.

² "The strength of the hyæna's jaw is such, that in attacking a dog, he begins by biting off his leg at a single snap." Buckland, *Reliquiæ Diluviana*, p. 23.

Teeth of Mammals.

In the lower jaw the sectorial tooth (*m* 1) manifests its true molar character by the presence of an additional pointed lobe on the inner side of the two lobes forming the blade at the forepart of the crown; the posterior, low, and large lobe of the tooth being also trituberculate, as in the dog. The last molar (*m* 2) has an oval crown with four small tubercles, resembling the penultimate lower molar in the dog, with which it corresponds.

The deciduous dentition consists, in the Viverrine family, of—

$$\begin{matrix} i & 3.3; & c & 1.1; & m & 3.3 \\ & 3.3; & & 1.1; & & 3.3 \end{matrix} = 28.$$

If the first permanent premolar has any predecessor, it must be rudimental, and disappear early in both jaws; the second premolar displaces the first normally developed deciduous molar; the third upper premolar displaces and succeeds the deciduous sectorial, which has a sharper and more compressed blade, and a relatively smaller internal tubercle, than the permanent sectorial. This tooth displaces the last deciduous molar, which is a tubercular tooth, resembling in form the first of the two upper permanent tuberculars; these coming into place without pushing out any predecessors, enter into the category of true molar teeth. In the lower jaw the third premolar displaces the deciduous sectorial, which has three trenchant lobes and a relatively smaller posterior talon than the permanent sectorial. The fourth premolar displaces the third or tubercular milk-molar. The permanent sectorial and tubercular molars displace no predecessors, and are therefore *m* 1 and *m* 2.

The alternate interlocking of the crowns of the teeth of the upper and lower jaws, which is their general relative position in the Carnivora, is well-marked in regard to the premolars of the *Viverridae* (fig. 106); as the lower canine is in front of the upper, so the first lower premolar (*p* 1) rises into the space between the upper canine and first upper premolar; the fourth lower premolar in like manner fills the space between the third upper premolar (*p* 3) and the sectorial tooth (*p* 4), playing upon the anterior lobe of the blade of that tooth which indicates by its position, as by its mode of succession, that it is the fourth premolar of the upper jaw. The first true molar below, modified as usual in the *Carnivora* to form the lower sectorial, sends the three tubercles of its anterior part to fill the space between the sectorial (*p* 4) and the first true molar (*m* 1) above. In the Musangs, the lower sectorial is in more direct opposition to its true homotype, the first tubercular molar in the upper jaw; and these Indian *Viverridae* (*Paradoxuri*) are the least carnivorous of their family, their chief food consisting of the fruit of palm-trees, whence they have been called "Palm-cats."

Canis.

The normal dental formula of the genus *Canis* is—

$$\begin{matrix} i & 3.3; & c & 1.1; & p & 4.4; & m & 2.2 \\ & 3.3; & & 1.1; & & 4.4; & & 2.2 \end{matrix} = 22 \text{ (fig. 107, } \textit{Canis}).$$

The incisors form a continuous series, describing the segment of a circle in both jaws, and progressively increase in size from the first

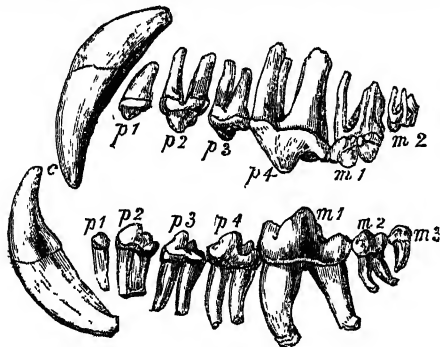

Fig. 107.

Teeth of the Dog.

to the third; the trenchant margin of the crown is divided by two notches into a large middle and two small lateral lobes. The canines (*c*) are curved, sub-compressed; the enamelled pointed crown forms nearly half the length of the tooth, and is smooth, without any groove. The premolars (*p*) have strong sub-compressed conical crowns gradually enlarging from the first to the third (*p* 3) in the upper jaw, and to the fourth (*p* 4) in the lower jaw, and acquiring one or two accessory posterior tubercles as they increase in size. The fourth upper premolar (*p* 4) presents a sudden increase of size, with its sectorial form; its blade is divided into two cones by a wide notch, the anterior cone being the strongest and most produced; the tubercle is developed from the inner side of the base of this lobe. The first and second upper molars (*m* 1 and 2) are tuberculate; but the second is very small, less than half the size of the first molar. The first true molar below (*m* 1) is modified to form the opposing blade to the sectorial tooth above; retaining the tuberculate character at its posterior half. The blade is divided by a vertical lineal

fissure into two cones, the posterior being the largest; behind this the base of the crown extends into a broad, quadrate, trituberculate talon. The second molar has two anterior cusps on the same transverse line, and a posterior broad flat talon; the last lower molar (*m*, 3) is the smallest of all the teeth.

The absence of a tuberculate molar in the lower jaw of the immature Dog, brings the character of the deciduous dentition of the genus *Canis* much closer to that of the typical members of the Carnivorous order, and affords an interesting illustration of the law that "unity of organization is manifested directly as the proximity of the animal to the commencement of its development." The succession of two tubercular molar teeth behind the permanent sectorial tooth in the adult, or permanent dentition of the lower jaw, carries the genus *Canis* farther from the type of its order, and stamps it with its own proper omnivorous character, and this contributes to adapt the Dog for a greater variety of climates and food, and of other circumstances, all of which tend, in an important degree, to fit that animal for the performance of its valuable services to man. In no other genus of quadruped are the jaws so well or so variously armed with dental organs; notwithstanding the extent of the series, the vacancies are only sufficient to allow the interlocking of the strong canines. These are efficient and formidable weapons for seizing, slaying, and lacerating a living prey: the incisors are well adapted, by their shape and advanced position, for biting and gnawing; the premolars, and especially the sectorials, are made for cutting and coarsely dividing the fibres of animal tissues, and the tuberculate molars are as admirably adapted for cracking, crushing, and completing the comminution of the food, whether of an animal or vegetable nature.

The dentition of the Weasel tribe (*Mustelidae*) is illustrated in Mustelinae. fig. 145, IV., *Mustela*, and by that of the Otter, fig. 108, which is a great aquatic Weasel or Polecat; its dental formula is—

$$\begin{matrix} i & 3.3; & c & 1.1; & p & 4.4; & m & 1.1 \\ & 3.3; & & 1.1; & & 4.4; & & 1.1 \end{matrix} = 36.$$

The canines (*c*) are shorter than those of the Fox, narrower than those of the Badger, larger and relatively thicker than those of the Martin-cat. The first premolar (*p* 1) in the upper jaw, which is absent in the Polecat and Weasel, is retained in the Otter (fig. 108) and is placed on the inner side of the canine; the sectorial premolar (*p* 4) has its inner lobe much more developed in *Lutra* than in *Putorius*, and the tubercular molar (*m* 1) is relatively larger. Similar modifications of these teeth distinguish the dentition of the lower jaw of the Otter, which agrees in the number and kind of teeth with that of the Polecat. The increased grinding surface relates to the inferior and coarser nature of the animal diet of the Otter, the back teeth being thus adapted for crushing the bones of fishes before they are swallowed.

In the Martin cats (*Mustela*), the little homotype of *p* 1 above is present in the lower jaw; in the bloodthirsty Stoats and Weasels, *p* 1 is absent in both jaws; as it is likewise in the great Sea-otter (*Enhydra*), in which also the two middle incisors are wanting in the lower jaw. In this animal the second premolar (*p* 3) has a strong obtuse conical crown, double the size of that of *p* 2; the third premolar (*p* 4) is more than twice the size of *p* 3, and represents the upper carnassial or sectorial strangely modified; the two lobes of the blade being hemispheric tubercles. The last tooth (*m* 1) has a larger crown than the sectorial, and is of a similar broad crushing form.

The *Mustelidae* present great constancy in regard to the number of their true molar teeth; with one exception, the Ratel (*Mellivora*), in which *p* 2 is absent below, they have one true molar on each side of the upper jaw, and two on each side of the lower jaw; the second of these has always a broad tubercular crown, like the one above. The upper true molar is supported by one inner, and sometimes by one (*Putorius*, *Gulo*), sometimes two (*Mustela*, *Lutra*, *Melphitis*) outer fangs. The second true molar below is also tubercular, but has a single fang. The crown of the first true molar below offers many gradations from the sectorial type, as manifested in *Putorius* and *Gulo*, to the tubercular type, as in the Taira, Ratel, and Sea-otter. The principal varieties occur, as usual, in the comparatively less important premolars; in the Martins and Gluttons, they are as numerous as in the Dog; the first, in both jaws, being implanted by a single fang; the rest by two, with the exception of the last above, which has three roots. In the Otter, we find the first premolar removed from the lower jaw; and the second (now the first) shows its true homology by its double implantation, as well as by the position of its crown behind the first in the upper jaw.

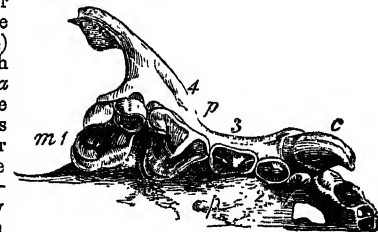

Fig. 108.

Teeth of Upper Jaw of the Otter.

¹ This law is defined and exemplified in the writer's *Lectures on the Invertebrate Animals*, pp. 868, 800, ed. 1843; p. 645, ed. 1855.

Teeth of
Mammals.

In the Stoats, Skunks, and Rats, the premolar series is further reduced by the loss of the anterior tooth (*p* 1) in both jaws, and by the diminution of the size of *p* 2, which thus becomes the first in both jaws, and is also now implanted by a single fang. In a South American Skunk, the second premolar disappears in the upper jaw, leaving there only the homologues of the third and fourth of the typical formula, *p* 4 being always the sectorial in the *Mustelidae*, as in other terrestrial Carnivora. This tooth, under all its modifications, retains the blade with the lobe, corresponding to the middle one in the feline sectorial, generally well-developed and sharp-pointed; the differences are principally manifested by the proportions of the inner tubercle, and the relative size of the third root supporting it. But the upper sectorial, being a premolar, and therefore requiring less modification of the crown to adapt it for its special functions, manifests a more limited extent of variety than the lower sectorial, which, being a true molar, requires greater modification of the typical form of its crown to fit it for playing upon the sectorial blade of *p* 4 above.

Melidae.

In this sub-family is comprised the European Badger (*Meles*), the Indian Badger (*Arctonyx*), and the American Badger (*Taxidea*); which, with respect to their dentition, stand at the opposite extreme of the *Mustelidae* to that occupied by the predaceous Weasel, and manifest the most tuberculate and omnivorous character of the teeth. The formula is—

$$i \frac{3.3}{3.3}; c \frac{1.1}{1.1}; p \frac{3.3}{4.4}; m \frac{1.1}{2.2} = 30.$$

The canines are strongly developed, well pointed, with a posterior trenchant edge; they are more compressed in *Arctonyx* than in *Meles*. The first lower premolar (*p* 1) is very small, single-fanged, and, generally, soon lost. The first above, corresponding with the second in the dog, is also small, and implanted by two connate fangs. The second upper premolar (*p* 3) has a larger, but simple, sub-compressed conical crown, and is implanted by two fangs. The third (*p* 4) repeats the form of the second on a larger scale, with a better developed posterior talon, and with the addition of a trituberculate low flat lobe, which is supported by a third fang; the outer pointed and more produced part of this tooth represents the blade of the sectorial tooth and the entire crown of the antecedent premolars. The true molar in *Meles* (*m* 1) is of enormous size compared with that of any of the preceding Carnivora; it has three external tubercles, and an extensive horizontal surface traversed longitudinally by a low ridge, and bounded by an internal belt, the "cingulum" of Illiger. In the Labrador Badger, the last premolar has a larger relative size, the part corresponding with the blade of the sectorial is sharper and more produced, and the internal tubercle has two lobes; the succeeding molar tooth is reduced in size, and its crown presents a triangular form. The first true molar below has its sectorial lobes better developed; these differences give the North American badgers a more carnivorous character than is manifested by the Indian or European species.

Procyonidae.

In other allied genera, which, like the badgers, have been grouped, on account of the plantigrade structure of their feet, with the bears, a progressive approximation is made to the type of the dentition of the Ursine species. The first true molar below soon loses all its sectorial modification, and acquires its true tubercular character; and the last premolar above becomes more directly and completely opposed to its homotype in the lower jaw. The Raccoon (*Procyon*), and the Coati (*Nasua*), present good examples of these transitional modifications; they have the complete number of premolar teeth, the dental formula being,

$$i \frac{3.3}{3.3}; c \frac{1.1}{1.1}; p \frac{4.4}{4.4}; m \frac{2.2}{2.2} = 40.$$

The development of the inner part of the crown of the last upper premolar, which constitutes the tubercle of the sectorial tooth, now produces two tubercles on a level with the outer ones which represent the blade; and the opposite premolar below (*p* 4), which is the true homotype of the modified sectorial above, begins to acquire a marked increase of breadth and accessory basal tubercles. All the lower premolars, as well as the true molars, have two fangs; the three first premolars above have two fangs, the fourth has three, like the two true molars above.

The dental formula of the Indian Benturong (*Arctictis*) and Kinjakou (*Cercopteles*) is—

$$i \frac{3.3}{3.3}; c \frac{1.1}{1.1}; p \frac{3.3}{3.3}; m \frac{2.2}{2.2} = 36.$$

Ursidae.

The essential characteristic of the dentition of the Bears (figs. 109 and 145, II.), *Ursus*, is the development, in the lower jaw, of the true molar teeth to their typical number in the placental *Mammalia*, and their general manifestation, in both jaws, of a tuberculate grinding surface; the premolar teeth are much reduced both in size and number. In the frugivorous Bears of India and the Indian Archipelago, the four premolars (*p* 1-4) are commonly retained longer than in the fiercer species of the northern latitudes. In the *Ursus labiatus*, the third small premolar above, and the second and third below, have each two connate fangs; the fourth premolar above presents three sub-equal obtuse tubercles supported by two distinct fangs. It is the only one of the four lower premolars retained in

the dentition of the great extinct *Ursus spelæus*; the first premolar co-exists with it in the *Ursus prisus*, as also commonly in the *U.*

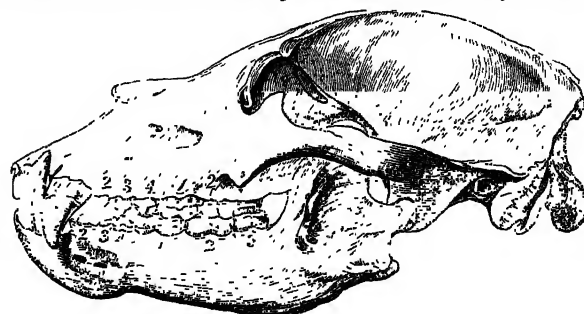

Teeth of
Mammals.

Fig. 109.

Dentition of the Bear (*Ursus*).

maritimus and *U. arctos*. The second lower premolar is soon lost in the Bears of temperate and northern latitudes, but is longer retained in the tropical species called "Sun Bears" (*Helarctos*, Horsfield). The first true molar (*m* 1) has a longer and narrower crown than the one above. The second true molar (*m* 2) has a narrow, oblong, sub-quadrated, tubercular crown, which, like that of the first true molar, is supported by two fangs. The crown of the third lower molar (*m* 3) is contracted posteriorly, and supported by two connate fangs; it is relatively smallest in the Sun-bears, and largest in the great *Ursus spelæus*. The dental formula of the genus *Ursus* is—

$$i \frac{3.3}{3.3}; c \frac{1.1}{1.1}; p \frac{4.4}{4.4}; m \frac{2.2}{2.2} = 42.$$

It is essentially the same both in number and kind of teeth as in genus *Canis*, but the individual or specific varieties, which in the Dog affect the true molar teeth, are confined in the Bears to the premolars. It would seem in the genus *Ursus* as if the preponderating size of the large tubercular true molars had tended to blight the development of the premolars.

In fig. 110 the deciduous teeth and their successors are figured,

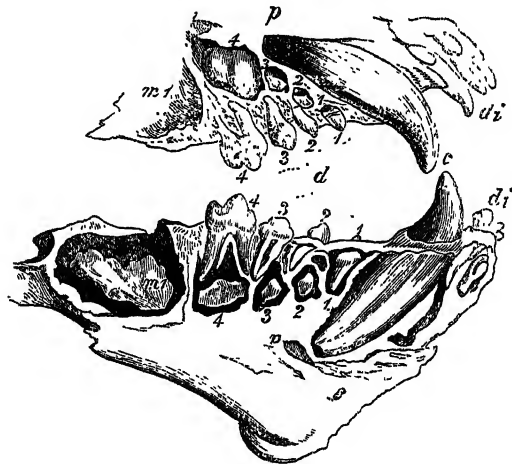

Fig. 110.

Milk-Teeth of the Bear.

as displayed by the removal of the outer wall of their sockets. The milk-molars, four in number on each side of both jaws, progressively increase from the first to the fourth. The characteristic relative position to them of the premolars is shown at *p* 2, 3, and 4. Behind these is shown the large formative cell of the first (*m* 1) of the true molar series.

A tendency to deviate from the feline number of the incisors is *Phocidae*. seen in the most aquatic and piscivorous of the Musteline quadrupeds, viz., the Sea-otter (*Enhydra*), in which species the two middle incisors of the lower jaw are not developed in the permanent dentition. In the family of true seals the incisive formula is further reduced, in some species even to zero in the lower jaw, and it never exceeds $\frac{3}{2}$. All the *Phocidae* possess powerful canines; and in the aberrant walrus (fig. 112), are they absent in the lower jaw, but this is compensated by the singular excess of development which they manifest in the upper jaw.

In the pinnigrade, as in the plantigrade, family of Carnivores, we find the teeth which correspond to true molars more numerous than in the digitigrade species, and even occasionally rising to the typical number, three on each side; but this, in the seals, is manifested in the upper, and not, as in the bears, in the lower jaw. The entire molar series usually includes five, rarely six, teeth on each side of

Teeth of
Mammals.

the upper jaw, and five on each side of the lower jaw; with crowns which vary little in size or form in the same individual. They are supported in some genera, as the Eared Seals (*Otaria*) and Elephant Seals (*Cystophora*), by a single fang; in other genera by two fangs, which are usually connate in the first or second teeth; the fang or fangs of both incisors, canines, and molars, are always remarkable for their thickness, which commonly surpasses the longest diameter of the crown. The crowns are most commonly compressed, conical, more or less pointed, with the "cingulum" and the anterior and posterior basal tubercles more or less developed; in a few of the largest species they are simple and obtuse, and particularly so in the walrus, in which the molar teeth are reduced to a smaller number than in the true seals.¹ In these the line of demarcation between the true and false molars is very indefinitely indicated by characters of form or position; but, according to the instances in which a deciduous dentition has been observed, the first three permanent molars in both jaws succeed and displace the same number of milk molars, and are consequently *premolars*; occasionally, in the seals with two-rooted molars, the more simple character of the premolar teeth is manifested by their fangs being connate, and in the *Stenorhynchus serridens* (fig. 111) the more complex character of the true molars (*m* 1 and 2) is manifested in the crown. There is no special modification of the crown of any tooth by which it can merit the name of a "sectorial" or "carnassial;" but we may point with certainty to the third molar above and the fourth below, as answering to those teeth which manifest the sectorial character in the terrestrial Carnivora.

The coadaptation of the crowns of the upper and lower teeth is more completely alternate than in any of the terrestrial Carnivora, the lower tooth always passing into the interspace anterior to its fellow in the upper jaw.

In the genus *Phoca* proper (*Calocephalus*, Cuv.) typified by the common seal (*Ph. vitulina*), the dental formula is—

$$i \frac{3.3}{2.2}; c \frac{1.1}{1.1}; p \frac{3.3}{3.3}; m \frac{2.2}{2.2} = 34.$$

In the *Phoca Caspica* the upper molars have commonly one accessory cusp before, and one behind, the principal lobe; the lower molars have one accessory cusp before, and two behind, the lower molars.

In the *Phoca Grælandica* the upper molars have no anterior basal cusp, and only one behind; the lower molars have two behind and one in front, except the first, which resembles that above, and like it has connate fangs.

The condition of the molar teeth is nearly the same in the *Phoca barbata*, but the crowns are rather thicker and stronger, and the three middle ones above have two posterior basal cusps feebly indicated, the same being more strongly marked in the four last molars below.

The following genera of Seals with double-rooted molars (*Pelagius*, *Stenorhynchus*) have four incisors above as well as below, i. e. $\frac{2.2}{2.2}$.

The allied sub-genus (*Ommatophoca*) of Seals of the southern hemisphere has six molar teeth on each side of the upper, and five on each side of the lower jaw, with the principal lobe of the crown more incurved. The two first molars above are closely approximated, but this may prove to be a variety.

In the *Stenorhynchus* the jaws are more slender and produced, and the molar teeth are remarkable for the long and slender shape of the principal lobe, and of the accessory basal cusps. The incisors

the external ones in the upper jaw are intermediate in size between the canines and the middle incisors.

In the *Stenorhynchus leptonyx* each molar tooth in both jaws is trilobed, the anterior and posterior accessory lobe curving towards the principal one, which is bent slightly backwards; all the divisions are sharp-pointed, and the crown of each molar thus resembles the trident or fishing-spear; the two fangs of the first molar in both jaws are connate. In *Stenorhynchus serridens* (fig. 111), the three anterior molars on each side of both jaws are four-lobed, there being one anterior and two posterior accessory lobes; the remaining posterior molars (true molars) are five-lobed, the principal cusp having one small lobe in front, and three developed from its posterior margin; the summits of the lobes are obtuse, and the posterior ones are recurved like the principal lobe. Sometimes the third molar below has three instead of two posterior accessory lobes. Occasionally, also, the second, as well as the first molar above, has its fangs connate; but the essentially duplex nature of the seemingly single fang, which is unfailingly manifested within by the double pulp-cavity, is always outwardly indicated by the median longitudinal opposite indentations of the implanted base. These slight and unessential varieties, presented by the specimens of the Saw-toothed Sterrink (*Stenorhynchus serridens*) brought home by the enterprising naturalist of Sir J. Ross' Antarctic expedition, accord with the analogous varieties noticed in other species of Seals, and show the inadequacy of such characters as marks of subgeneric distinction.

In the genus *Otaria* the dental formula is—

$$i \frac{3.3}{2.2}; c \frac{1.1}{1.1}; p \frac{3.3}{3.3}; m \frac{3.3}{2.2} = 36.$$

The two middle incisors are small, sub-compressed, with the crown transversely notched; the simple crowns of the four incisors below fit into these notches; the outer incisors above are much larger, with a long-pointed conical crown, like a small canine. The true canine is twice as large as the adjoining incisor, and is rather less recurved. The molars have each a single fang.

In the great proboscidean and hooded Seals (*Cystophora*), the incisors and canines still more predominate in size over the molars; but the incisors are reduced in number, the formula here is—

$$i \frac{2.2}{1.1}; c \frac{1.1}{1.1}; p \frac{3.3}{3.3}; m \frac{2.2}{2.2} = 30.$$

All the molars are single-rooted, and all the incisors are lanianiform. The two middle incisors above and the two below are nearly equal; the outer incisors above are larger. The canines are still more formidable, especially in the males; the curved root is thick and sub-quadrate. The crowns of the molar teeth are short, sub-compressed, obtuse; sometimes terminated by a knob and defined by a constriction or neck from the fang; the last is the smallest.

In the Walrus (*Trichechus rosmarus*, fig. 112), the normal incisive formula is transitorily represented in the very young animal, which has three teeth in each intermaxillary bone and two on each side of the fore-part of the lower jaw; they soon disappear, except the outer pair above, which remain close to the intermaxillary suture, on the inner side of the sockets of the enormous canines, and seem to commence the series of small and simple molars which they resemble in size and form. In the adult there are usually three molars or premolars on each side, behind the permanent incisor, and four similar teeth on each side of the lower jaw; the anterior one passing into the interspace between the upper incisor and the first molar, and therefore being the homotype of the molar. In a young walrus' skull with canine tusks eight inches long, the writer has seen a fourth upper molar (fifth including the incisor) of very small size, about a line in breadth, lodged in a shallow fossa of the jaw, behind the three persistent molars. The crowns of these teeth must be almost on a level with the gums in the recent head; they are very obtuse, and worn obliquely from above down to the inner border of their base. The molars of the lower jaw are rather narrower from side to side than those above, and are convex or worn upon their outer side. Each molar has a short, thick, simple and solid root.

The canines (*c*) are developed only in the upper jaw, but are of enormous size, descending and projecting from the mouth, like tusks, slightly inclined outwards and bent backwards; they present an oval transverse section, with a shallow longitudinal groove along the inner side, and one or two narrower longitudinal impressions upon the outer side; the base of the canine is widely open, its growth being uninterrupted.

The food of the walrus consists of sea-weed and bivalves; the

Teeth of
Mammals.

Fig. 111.

Dentition of the Saw-toothed Seal. (*Stenorhynchus*).

(fig. 111) have sharp conical recurved crowns, like the canines, and

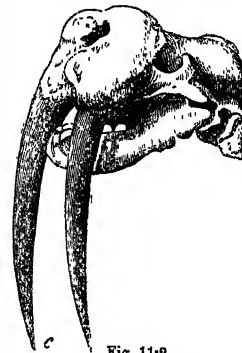

Fig. 112

Skull and Teeth of the Walrus

¹ The relation of *Trichechus* to the *Phocidae* is analogous to that of *Machairodus* to the *Felidae*, and also, in the simplification of the molars, to that of *Proteles* to the *Canidae*.

Teeth of
Mammals.Machairo-
dus.

molars are well adapted to break and crush shells; and fragments of a species of *Mya* have been found, with pounded sea-weed, in the stomach. The canine tusks serve as weapons of offence and defence, and to aid the animal in mounting and clambering over blocks of ice.

A large extinct carnivorous animal (*Machairodus*, fig. 145, VI.), had the upper canine teeth (*c*) developed to almost the same disproportionate length as in the walrus, by which they were also compelled to pass outside the lower jaw when the mouth was shut. But these teeth were shaped after the type of the feline canines, only with more compressed and trenchant crowns; and they were associated with other teeth in number and kind demonstrating the due affinity of the *Machairodus* to the genus *Felis*.

The molar series of the upper jaw includes three teeth on each side, answering to the last two premolars (*p* 3 and *p* 4) and to the small tubercular tooth (*m* 1) in the lion. The inner tubercle of the carnassial tooth (*p* 4) is much less developed than in *Felis*. The molar series of the lower jaw accords with that of the lion, but *p* 3 is relatively very small in the South American *Machairodus* (*M. neogaeus*).

The symphysis of the lower jaw presents a rapid increase in vertical diameter, whilst a depression on the outer side, between the canine and the first molar, indicates the part which received the long upper canine. The lower canine is much reduced in size, and appears to form the exterior tooth of the series of incisors; these are, however, six in number in the lower as in the upper jaw.

Both the anterior and posterior margins of the long upper falciform canines are finely serrated in *Machairodus*. The fossil teeth of this kind from Kent's Hole, Torquay, indicate a species of *Machairodus*, as big as the lion, and distinct from that of the Italian pliocene deposits, on which Cuvier founded his "*Ursus cultridens*."

Hyænodon.

In more ancient tertiary formations, remains of carnivorous mammals have been found with the three true molar teeth as expressly modified for the division of flesh, and as worthy the express term of "sectorials" or "carnassials," as the teeth so called in the lion and other felines. And these teeth were associated with conical premolars, long canines, and short incisors, so as to exemplify the typical formula, *e. g.*—

$$\begin{matrix} 33 & c & 11 & p & 44 & m & 33 \\ 33 & & 11 & & 44 & & 33 \end{matrix} = 44.$$

The extinct *Hyænodon* and *Pterodon* of the upper eocene formations of Hampshire, and of parts of France, manifest this interesting and instructive character of dentition.

A reduced view of the lower jaw of the *Hyænodon Requieni* is given in fig. 113. After the canines (*c*) come four successively

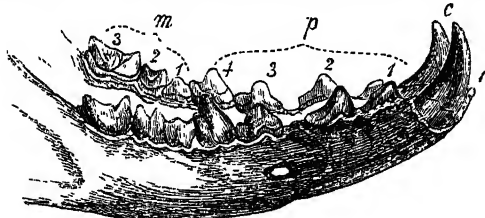

Fig. 113.

Dentition, Lower Jaw, of *Hyænodon*.

enlarging conical compressed premolars (*p* 1-4); then, instead of a single carnassial representing the first true molar, there are three of these singularly modified teeth—the first (*m* 1) being of suddenly small size, as compared with the antecedent premolar, and obviously illustrating its true nature as a continuation of the deciduous series, with which, doubtless, it agreed in size. It became a permanent tooth only because there was no premolar developed beneath it, so as to displace it. The succeeding carnassial true molars (*m* 2 and 3) progressively increase in size. The symbols in fig. 111 denote the homologies of the teeth. The marks of abrasion on the lower teeth

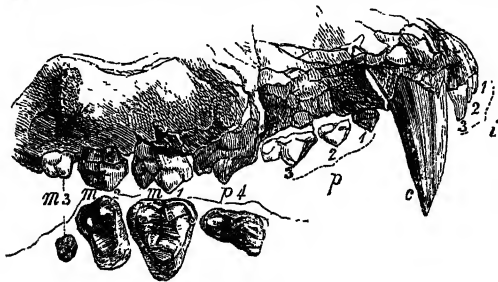

Fig. 114.

Dentition, Upper Jaw, of *Amphicyon*.

in the *Hyænodon* prove the upper series to have been the same in number.

The obvious number of premolars in the *Hyænodon* negatives the notion entertained by De Blainville, that it was a marsupial carnivore.

Teeth of
Mammals.Amphi-
cyon.

A second form of equally ancient Carnivore was a mixed-feeding animal, allied to the Viverridae and to the Dog tribe, the true molars presenting the tuberculate modification, and the typical number and kinds of teeth being functionally developed, as in the *Hyænodon*. The series in the upper jaw are shown in fig. 112. The term "tubercular" is as applicable to the three true molars of the *Amphicyon* (*m* 1, 2, 3) as the term "carnassial" is to those of the *Hyænodon*.

Structure
Carnivora.

The teeth of the *Carnivora*, with the exception of the aberrant amphibious forms, so closely correspond in their intimate structure, both with each other and with those of the human subject, as to require here only a brief and general notice. They all enter into the category of "simple teeth," that is, the dentine or main body is not penetrated by folds of the other component tissues, but has an even exterior, covered, at the part forming the crown, with enamel, and having a general outer investment of cement, the coronal layer forming too thin a film to manifest any of the radiated cells. The dentine is of the kind called "hard or unvascular;" the tubuli are rather finer than in the human teeth; they have the same general direction from the pulp-cavity, but present stronger primary curvatures, more frequent dichotomous divisions, and more numerous minute lateral branches, which latter usually curve from the trunks at right angles. The dentinal compartments are subhexagonal, about $\frac{1}{800}$ th of an inch in diameter, with the peripheral contour forming almost a regular curve. In the Seals the dentine forms usually a smaller proportion of the tooth than in the terrestrial *Carnivora*; the characteristic thickness of the roots in this family is principally due to the thick covering of cement, and the pulp-cavity is usually closed by a more than usual quantity of the osteo-dentine. The tubes in the Seal's molar describe very strong and irregular curves on leaving the pulp-cavity; but when within a third of the distance to outer surface, they fall into more parallel and regular undulations; they are $\frac{1}{1000}$ th of an inch in diameter, and the interspace between two tubes is about $\frac{1}{1000}$ th of an inch in width.

The tubes dichotomise less frequently and less regularly than in the teeth of the Dog or Hyæna, but send off from both sides extremely numerous short branches, which bend almost transversely across the interspaces, and the side branches are occasionally sent off in greater abundance along lines parallel with the outer contour of the teeth, giving the appearance of opaque striæ, or concentric layers, to polished sections of the dentine. The dentinal tubes resolve themselves at their extremities into rich tufts of curved branches, which terminate in a layer of minute cells at the crown, and in the root communicate with the radiated cells of the cement.

In the molar teeth of the *Otaria jubata*, the tubes, proceeding in the long axis of the crown, are, on the peripheral half of the dentine, nearly parallel; towards the side of the crown they proceed in more zigzag, almost angular curves, and appear to cross each other, conspicuous branches being continued from the angles; the interspaces of the tubes were about $\frac{1}{800}$ th of an inch in width. The dentinal compartments are more numerous and less regular than in the teeth of the ordinary *Carnivora*; and their contour is more obscured by the deeper curves and more numerous branches of the dentinal tubes.

The enamel of the teeth of the *Carnivora* is extremely dense and brittle; it consists of fibres similar to those in the Human teeth, but relatively smaller, as, for example, in the large canines of the Tiger, and the molars of the Hyæna; the transverse striæ are also less distinct. In the molar of the *Otaria*, the enamel-fibres are very distinct, placed at right angles to the plane of the crown, and less curved than in Man or the *Quadrumanus*; instead of the transverse striæ, they present a minute granular structure.²

The cap of enamel with which the teeth of the Walrus are at first tipped, is soon worn off; and, except at the abraded surface, the rest of the tooth—both tusks and molars—is thickly coated with cement. The dentine closely corresponds with that in the ordinary Seals; in the molar teeth the tubes present the same diameter, the same interspaces, and undulating curvatures; but their dichotomous divisions are more marked. In the canines the lateral branches terminate in minute opaque cells, dispersed throughout almost the whole dentine, but most numerous and conspicuous near its periphery, where the dentine is defined by a distinct layer of these cells; only a third part of the periphery of the canine is composed of true dentine, the central third part of the tooth is filled up by osteo-dentine, which, as in the teeth of the Cachalot, often projects in irregular rounded masses into the short and wide basal pulp-cavity. The whole mass, indeed, of the osteo-dentine consists of numerous independent calcifications of the pulp, having as many distinct centres, usually hollow, and producing, when the substance is examined by the naked eye, the appearance which Cuvier has compared to "pudding-stone." The central cavities are for the most part associated together and with the pulp-cavity by medullary canals. The tubes radiate from these central cavities in all directions, with sub-parallel, diverging curva-

¹ *Ossemens Fossiles*, 4to, 1824, vol. v. pt. ii. p. 517.² Retzius failed to detect any true enamel in the teeth of the *Phoca anellata*.

Teeth of
Mammals.

tures, dividing, subdividing, and sending off numerous branches, which anastomose with those of the adjoining masses, and, where these are situated next the dentine, with the tubes of that tissue. In each lobe of the osteo-dentine the concentric rings parallel with the contour of the central medullary cavity are well marked. Myriads of minute calcigerous cells are dispersed throughout the osteo-dentine. The pulp-cavity of the incisor and molar teeth is filled up by a smaller quantity of the osteo-dentine. Minute vascular canals convey the capillary blood-vessels to this structure, from the vascular membrane attached to the solid base of the molars, and in the tusks, from the persistent pulp, which fills the basal cavity.

The cement of the Morse's teeth is distinguished from the osteo-dentine by its continuous uniform structure, by the absence of the detached centres, and their concentric lines; but the radiated cells are disposed in regular layers, concentric and parallel with the contour of the body of dentine; the radiating tubes, from the cells forming the layer next the dentine, communicate freely with the peripheral ramifications of the dentinal tubes, and also with the proper cemental tubes, which are disposed vertically to the plane of the cement. Indeed, the evidence of an intercommunicating system of canals, too minute for the gross fluid of the circulating system, is most striking and universal throughout the substance of both the tusks and small teeth of the Walrus. Vascular canals are, however, present in the cement as in the osteo-dentine, from the capillaries in which it may be presumed that the colourless plasma is elaborated, which meanders through the minuter systems of cells and tubes.

Ungulata,
or
Herbivora.

The first forms of vegetable-eating mammals of which we have cognizance, those, viz., that have been restored from fossil remains discovered in the eocene or oldest tertiary deposits, have presented a dentition conformable, in number and kind of teeth, to the typical condition in the Placental Diphyodont series.

The chief modifications are presented by the grinding surface of the molar teeth. In the *Hyracotherium* (e.g., fig. 115) the grinding surface supports four principal cusps, each transverse pair (*a, c, b, d*) being connected by a ridge which is raised midway into a smaller conical tubercle, and the crown is girt by a cingulum.

In the *Anoplotherium* (fig. 116) the crown is divided into a front (*f, c*) and a back (*f, d*) lobe by a valley (*e*), extending from the inner side, two-thirds across, contracting as it penetrates. A second valley (*g, i*) crosses its termination at right angles, and forms a curved depression in each lobe, concave towards the outer side of the crown,—this side being impressed by two parallel excavations (*f, f*). There is a large conical tubercle (*m*) at the wide entry of the valley (*e*).

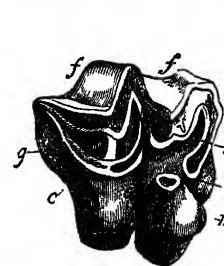

Fig. 116.

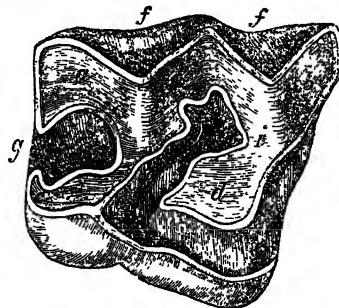

Upper Molar of *Anoplotherium*.

Fig. 117.

Upper Molar of *Palaeotherium*.

The two points of the outer continuous border formed by the two outer

lobes (*a, v*) are first abraded; those of the inner lobes (*c, d*) are next abraded; and thus a double crescentic field of dentine is exposed, with a detached island on the summit of the internal cone (*m*). This, afterwards, from the minor depth of the valley in front of its base, becomes blended with the lobe (*d*). In the *Palaeotherium* (fig. 117)

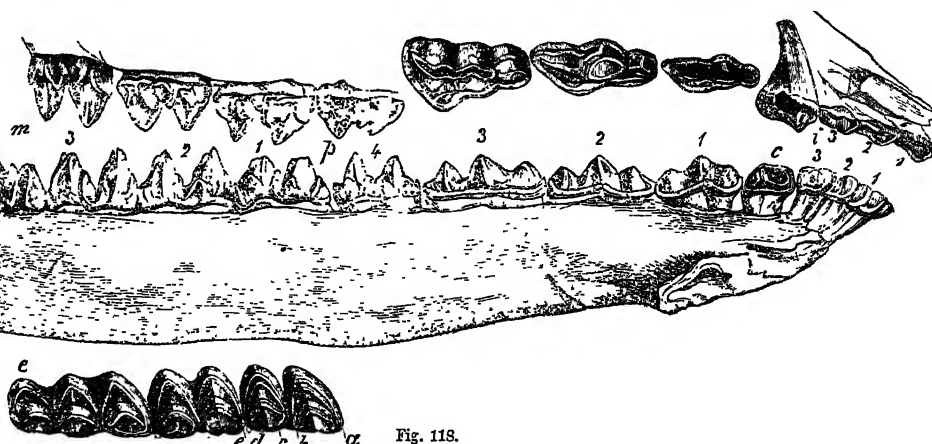

Teeth of
Mammals.

Fig. 118.

Dentition of the *Dichodon cuspidatus*.

the crown of the molar is divided into an anterior (*b, d*) and posterior (*a, c*) part by an oblique fissure (*e*), continued from near the middle of the inner surface of the crown obliquely outwards and forwards, two-thirds across the tooth. Each division is subdivided partially into two outer (*a* and *b*) and two inner (*c* and *d*) lobes; the anterior division by the terminal expansion (*i*) of the fissure (*e*), the posterior one by the valley or fissure (*g*). The lobes (*c* and *d*) are bordered near their base by a ridge.

The first of the above types (fig. 115) of the upper grinders of the eocene *Herbivora* is continued into, or governs, with minor modifications, the corresponding teeth of the *Cheropotamus*, *Anthracotherium*, and the existing Hog-tribe and Hippopotamus. The second or *Anoplotherian* type (fig. 116) is continued into the *Dichodon*, *Dichobunus*, and the existing Ruminant dentition. The third (fig. 117) is the fundamental pattern of the upper molars of the tribes of the Horse and Rhinoceros.

A fourth form of eocene grinder, that of the genus *Lophiodon*, is very nearly allied to the *Palaeotherium*, but the more complete union of the lobes *a, c*, and that of the lobes *b, d*, gives a more decided transversely-ridged character to the crown, and this type was carried on in the *Dinotherium* (fig. 136) and the existing Tapirs.

The space allotted to this article limits the selection of examples of the ungulate dentition to a few of the best-marked modifications, and the first of these forms a transitional step between the *Anoplotherium* and the *Ruminantia*.

The dentition in question is that of an extinct genus, the remains of which occur in the upper eocene of Hampshire, and which the writer has described under the name of *Dichodon cuspidatus*² (fig. 118). The dental formula is—

$$i \frac{3.3}{3.3}; c \frac{1.1}{1.1}; p \frac{4.4}{4.4}; m \frac{3.3}{3.3} = 44.$$

The crowns of these different kinds of teeth are of nearly equal height, and there is no break in the series.

The incisors (*i* 1, 2, 3) have low and broad trenchant crowns. The canine (*c*) closely resembles them, but is a little larger, and with a low point: it is, however, more trenchant than piercing. The first (*p* 1), second (*p* 2), and third (*p* 3) premolars, have their crown much extended from before backwards, with three progressively more developed and pointed compressed cusps on the same line; to which is added, in the upper jaw, an inner ridge, developed in the third premolar (*p* 3) into an inner posterior cusp. The fourth premolar (*p* 4) has a thicker and shorter crown with two pairs of cusps. The upper true molars (*m* 1, 2, 3) have the two pairs of cusps sharp and pointed, with a series of five low accessory points developed from the outer part of the cingulum. The lower molars (*m* 1, 2, 3) have as complex crowns as the upper ones, but with the accessory basal points (*a, b, c, e*) developed from the inner, instead of the outer side of the crown, and with the convex sides of the chief cusps turned in the opposite direction to those above. In fig. 116 the outer side of the true molars, of the last premolar, of the canine, and of the incisors, is shown, together with the grinding surface of the three anterior premolars in the upper jaw. The inner surface of the

¹ "L'ivoire des défenses du Morse est compact, susceptible d'un poli presque aussi beau que celui de l'hippopotame mais sans stries; la partie moyenne de la dent est formée de petits grains ronds placés pêle mêle, comme le Cailloux dans la pierre appelée *Poudingue*; c'est ce qui le caractérise. Les dents molaires de cet animal ont leur axe composé des mêmes petits grains que celui des défenses. Elles n'ont aucun cavité dans leur intérieur."—Cuvier, *Leçons d'Anat. Comparée*, tom. iii. (1805), p. 106.

Teeth of
Mammals.
Order
Rumi-
nantia.

entire series of the lower teeth is shown, together with the grinding surface of the three true molars of the last (*m* 3) here supports a third pair of lobes (*e*). As compared with the anoplotherian molar (fig. 116), the outer lobes (*a*, *b*) of that of the *Dichodon* (fig. 119) are thicker and sharper; the inner ones (*c*, *d*)—especially the latter—are developed to an equality with the outer ones, and more distinctly separated from them. The valley (*m*) extends across the whole breadth of the tooth, and is crossed at right angles by the fore-and-aft doubly-curved valley (*g* and *i*).

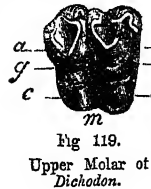

Fig. 119.
Upper Molar of
Dichodon.

The modification of the upper molars of the existing Ruminant quadrupeds consists in the lower and less pointed lobes of the crown, the unworn summits of which are at first rather trenchant, like curved blades, than piercing. They are soon abraded by mastication, and present the crescentic lobes of dentine (*a*, *b*, *c*, *d*) shown in fig. 120. The transverse double-crescentic valley (*g*, *i*) contains a thicker layer of cement, and forms two detached crescents in worn teeth. The premolars resemble in structure one half of the true molars. The upper incisors, the upper canine, and the first premolar of both jaws, are not developed in the typical Ruminants, the dental formula of which is—

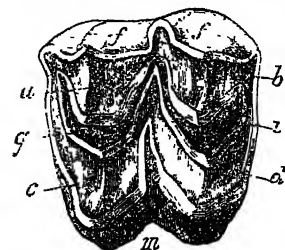

Fig. 120.
Upper Molar of *Megaceros*.

upper canine, and the first premolar of both jaws, are not developed in the typical Ruminants, the dental formula of which is—

$$i \frac{0.0}{3.3}; c \frac{0.0}{1.1}; p \frac{3.3}{3.3}; m \frac{3.3}{3.3} = 32.$$

The gazelle, the sheep, the ox—respectively representing the families *Antilopidae*, *Ovidae*, and *Bovidae*, which are collectively designated the "hollow-horned ruminants"—all present this formula. It likewise characterises many of the solid-horned ruminants, or the deer tribe (*Cervidae*), the exceptions having canine teeth in the upper jaw of the male sex, and sometimes also in the females, though they are always smaller in these.

The upper canines attain their greatest length in the small ruminants called Musk-deer, and especially in the typical species (*Moschus moschiferus*, fig. 145, VII.). These teeth, indeed, in the male *Moschus* present proportions intermediate between those of the upper canines of the Machairodus and of the Morse. The inverse relationship in the development of teeth and horns, exemplified by the total absence of canines in the Ruminants with persistent and typical horns, by their first appearance in the periodically hornless deer, and their larger size in the absolutely hornless Musks, is further illustrated by the presence not only of canines, but of a pair of lanariform incisors in the upper jaw of the Camelidae.

Camelidae

In the Camel and Dromedary the upper canines are formidable for their size and shape, but do not project beyond the lips like the tusk of the Musk-deer; they are more feeble in the Llamas and Vicuñas, and are always of smaller size in the females than in the males. The inferior canines, moreover, retain their lanariform shape in the *Camelidae*, and are more erect in position than in the ordinary Ruminants. They are separated by a short diastema from the incisors in the *Auchenia*.

The true nature of the corresponding canines in the ordinary Ruminants, in which they are procumbent, and form part of the same series with the incisors, is always indicated by the lateness of their development, and often by some peculiarity of form. Thus in the *Moschus* (fig. 145, VII. c) they are smaller and more pointed than the incisors, and in the Giraffe they have a much larger crown, which is bilobed. The lanariform tooth in the premaxillary bone of the *Camelidae*, which represents the upper and outer incisor, is smaller than the true canine which is placed behind it in the Camel and Dromedary; but in the *Vicuña* it is as large as, or larger than, the true canine.

Most of the deciduous molars of the Ruminants resemble in form the true molars; the last milk-molar, for example (fig. 121, *d* 4), in the lower jaw, has three lobes like the last lower true molar (*m* 3). The deciduous molars in existing true Ruminants are three in number on each side, and, being succeeded

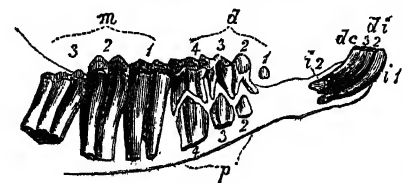

Fig. 121.

Deciduous and Permanent Teeth of a Sheep.

by as many premolars, the ordinary permanent molar formula is—

$$p \frac{3.3}{3.3}; m \frac{3.3}{3.3};$$

but there is a rudiment of *d* 1 in the embryo fallow-deer, and in one of the most ancient of the extinct Ruminants (*Dorcatherium*, Kaup) the normal number of premolars was fully developed.

Teeth of
Mammals.

The birth and growth of a young Giraffe at the Zoological Gardens of London, enabled the writer to make the following observations on the course of development and succession of the teeth in this Ruminant, which is the largest existing species of its order. The four middle deciduous incisors began to cut the gum one week after birth, and their crowns were entirely extricated at the end of four weeks, at which time the summit of the crowns of both the first and second deciduous molars were visible. At two months the third incisor had cut the gum; at three months the third deciduous molar, and at four months a fourth molar were in place; the latter being the first of the permanent series of true molars.

The progress of shedding the deciduous teeth was traced by observation of the mother Giraffe. She arrived at the Zoological Gardens in May 1836, and was then about eighteen months old, and had all the deciduous series, with the first permanent true molars. The two middle deciduous incisors were shed in the month of March 1838, the second incisor on each side in the following July, the first deciduous molars in October, and the second deciduous molars in November and December of the same year. At this time the second true molars came into place, the last true molars began to appear above the gum in August 1839, and the last deciduous molar was replaced by the third premolar before the end of that year. The shedding of the whole deciduous series was completed by the fall of the canines in the female Giraffe at the period of the birth of her second fawn in May 1841, when she must have been six years and a half old; the large bilobed crowns of the permanent canines were not completely in place until September 1841.

The same noble menagerie has afforded the opportunity of recording the following state of the first dentition of the *Dromedary* :—

In the new-born animal the six deciduous upper incisors present a larger size than any rudiments of these that have been discerned in the fetus of ordinary Ruminants, and, as was discovered by subsequent dissection, these transitory incisors leave conspicuous alveoli in the premaxillary bones. The canine and first functional deciduous molar are small; the second and third deciduous molars are large, bilobed, and each lobe is bicrescentic. In the lower jaw the functional milk-teeth consist of the six incisors and two canines, one on each side, all with the overlapping leaf-shaped crowns. The functional molars are but two in number, in each ramus of the jaw. The first small, simple, conical, compressed, notched behind; the second very large, and three-lobed, each lobe bicrescentic, and the last lobe the largest. The middle incisors are relatively larger in the deciduous than in the permanent series, as compared with the outer ones and the canine in the ordinary Ruminants. The Giraffe deviates furthest from the typical proportions of these teeth in the superior expanse of the bilobed crown of the permanent canine, but it is interesting to find that the deciduous canine, though its crown is also bilobed, is relatively smaller in proportion to the incisors, and thus shows a less amount of deviation from the common type. The third molar is the last inferior true molar. This tooth in the great extinct *Sivatherium* retained more of the shape of its deciduous analogue, the last milk-molar, than is usually seen in existing species of *Ruminantia*.

The characteristic complexity of the molar teeth of a Ruminant is seen in most of the deciduous series, but in the permanent series only in the three posterior teeth of both upper and lower jaws, which are the true molars; the three first, or premolars, having more simple crowns than those which they displace. The complexity in question is the result of peculiar plications of the formative capsule, some of which are longitudinal, or project inwards from the sides of the capsule, and form peninsular folds of enamel upon the grinding surface of the tooth, whilst others depend vertically from the summit of the matrix into the body of the tooth, and form islands of enamel when the crown begins to be worn. Of the longitudinal folds, two in the upper true molars are external, broad, but shallow, and often sinuous, and one is internal, narrow, and deep, extending quite across the summit of the crown of the tooth, and decreasing in depth towards the base of the crown. The corresponding fold of enamel in the completed tooth, accordingly, extends more or less across the crown, from within outwards, as the tooth is less or more worn. The whole circumference of this complex molar is also invested by a coat of enamel and a thinner layer of cement. In some Ruminants, *e. g.* Ox, Deer, and Giraffe, a small vertical column (fig. 120, *m*) is developed at the internal interspace of the two lobes of one or more of the upper true molars, varying in height, and rarely reaching the summit of the new-formed crown. Different genera of Ruminants also differ in the depth and sinuosity of the two outer longitudinal folds, and in the depth and complexity of the two vertical folds, which likewise are united in some species by a longer common base than in others, producing thereby a continuity of the enamel, and complete antero-posterior bisection of the grinding surface during a longer period of attrition. The upper molars also differ in their breadth, or antero-posterior diameter, as compared with their thickness or transverse diameter; but as the summit of the crown is always relatively broader in proportion to its thickness, care must be taken to compare teeth of the different species that have been worn to the same extent, or to allow for the difference.

Develop-
ment.

Teeth of Mammals.

In the Ox the outer contour of each lobe of the upper molars is more sinuous than in the Antelope or Sheep, the middle convexity being more prominent and the lateral depressions deeper. The crescentic islands are not so wide as in the larger Antelopes, and the secondary terminal indentations are less marked at the forepart of the island. The small internal accessory column (*e*) forms part of the periphery of the grinding surface at the inner interspace of the lobes, when the crown has been worn down about half an inch, from which part it decreases in size to the beginning of the fangs.

In the Deer (*Cervus*), the inner crescentic subdivision of each lobe is thicker transversely than in the *Bovidae*. In the great extinct Irish Deer (*Megaceros*, fig. 120), which has molar teeth as large as those of the Aurochs, the crescentic islands are simple, narrow, and more curved or bowed than in the Ox, and in consequence of the later division of the vertical fold of the capsule, the cemental cavity of each is continued into the other until a later period of the attrition of the crown, as shewn in the upper molar (fig. 120). In the Elk (subgenus *Alces*), the central crescents are continuous for a still longer period, and the median longitudinal fold, which divides the crown transversely, retaining its full breadth for a greater extent. The crown of the molar is divided, during a longer period of attrition, by a crucial incision. The molars of the Camel present the most simple condition of the Ruminant type of these teeth; the transverse fold dividing the crown being short, the dentine of the two lobes soon forms a continuous tract. The common base of the crescentic vertical folds of the capsule being likewise short, the enamel islands are soon separated from each other. They include a shallow or narrow crescentic cavity, with a simple but slightly sinuous contour. The two outer shallow longitudinal depressions of the crown have no middle rising; and there is no columnar process at the interspace of the two inner convexities. Bojanus has well illustrated these characteristics of the upper molars of the Camel in his memoir on the *Merycotherium*,¹ a large extinct Cameloid genus of *Ruminantia*, founded on remains discovered in the drift of Siberia; and he has extended the comparison to the Sheep, the Elk, and the Ox.

Cuvier compares the lower molars of the Ruminants to the upper ones reversed. In the lower true molars the single median longitudinal fold is external, and divides the convex outer sides of the two lobes. The base of the fold extends, in some species, across the molar for some distance before it contracts in breadth, retreating towards the outer side, and the two lobes of the crown accordingly continue to be completely divided for a longer period, as in the Elk and Giraffe. The inner surface of the molar is gently sinuous, the concavities being rarely so deep as those of the outer surface of the upper molars. The lower molars are always thinner, in proportion to their breadth, than those above, and the crescentic islands are narrower and less bowed. The differences which the lower molars present in different genera of Ruminants are analogous to those in the upper molars, but are less marked. The accessory small column, when present, as in *Bos*, *Urus*, *Megaceros*, and *Alces*, is situated at the outer interspace of the convex lobes, and nearer the base in the *Cervidae* than in the *Bovidae*. It is not developed in the Antelopes, Sheep, or Camel, and is wanting in most of the smaller species of Deer. The last true molar of the lower jaw is characterized in all Ruminants by the addition of a third posterior lobe. This is very small and simple in the Camel and the Gnu, is relatively larger in the *Bovidae* and *Cervidae*, and presents, in the *Megaceros* and *Sivatherium*, a deeper central enamel island or fold, which also characterizes the smaller third lobe in the Giraffe. The lower molars of the genus *Auchenia* are peculiarly distinguished by the vertical ridge at the forepart of the anterior lobe, which does not exist in the Camels of the Old World.

In all Ruminants, the outer contour of the entire molar series is slightly zigzag, the anterior and outer angle of one tooth projecting beyond the posterior and outer angle of the next in advance. The premolars are smaller and more simple than the molars, with which they form a continuous series in the true Ruminants. In the upper jaw they are not divided into two lobes by an internal cleft, but resemble a single lobe of the true molars, of greater breadth than thickness, with a single central crescentic island, and usually with an internal nasal ridge.

The central crescents have a more complex contour in *Megaceros* than in *Bos*, and the first premolar, which is always the smallest, is relatively larger in the Deer than in the hollow-horned Ruminants. In the small Musk-deer, the crescentic enamel-island is reduced to a small internal notch or fold, and the outer border of the crown is trenchant and pointed. In the lower jaw the premolars decrease in size from the third to the first, which has usually a compressed conical crown, with a sinuous inner surface. The second and third premolars have two deeper notches on the inner side, and a small second hinder lobe seems to be slightly marked off by a vertical depression on the outer side of the crown. All the three lower premolars have compressed, sub-trenchant, and pointed crowns in the small Musk-deer (*Tragulus*). The true Musk (*Moschus*) more resembles the

ordinary Deer in its premolars. The aberrant *Camelidae* deviate most from ruminant type in the position, shape, and number of the premolars.

The extinct *Cheropotamus*, *Anthracotheirus*, *Hyopotamus*, and *Hippohyus*, had the typical dental formula, and this is preserved in the existing representative of the same section of non-ruminant Artiodactyles, the Hog. The permanent dental formula of the genus *Sus* is illustrated in fig. 20.

The upper incisors (fig. 20, *i*) decrease in size from the first to the third; the first has a short, strong, obtusely-pointed crown, obliquely levelled from the outside of the base to its apex, which inclines towards and touches that in the other premaxillary by its produced inner part; the crown, before it is worn, presents a semi-lunar depression on its inner side, the concavity of which, directed towards the base, receives a tubercular prominence, it is implanted by a short, thick, curved fang; this incisor is relatively larger in the *Sus larvatus* than in the *Sus scrofa*; the basal line of the enamel is extremely irregular; that substance extends more than an inch upon the outer side of the tooth, but only two or three lines on the inner side, where an angular piece seems to be cut out. The second incisor in the common Hog has a crown as broad as the first, but shorter and thinner; its edge is trenchant and dentated, but is soon worn down; in this state the abraded surface of both incisors shows a dark mark in the centre. The third is a very small tooth, a little removed from the second. The lower incisors are long, sub-compressed, nearly straight; the second is rather larger than the first; the third is the smallest, as in the upper jaw.

The upper canines, in the Wild Boar (fig. 20, *c*) curve forwards, outwards, and upwards; their sockets inclining in the same direction, and being strengthened above by a ridge of bone, which is extraordinarily developed in the Masked Boar of Africa. The enamel covering the convex inferior side of this tusk is longitudinally ribbed, but is not limited to that part; a narrow strip of the same hard substance is laid upon the anterior part, and another upon the posterior concave angle forming the point of the tusk, which is worn obliquely upwards from before, and backwards from that point. In the Sow the canines are much smaller than in the Boar. Castration arrests the development of the tusks in the male.

The teeth of the molar series progressively increase in size from the first to the last. The first premolar (fig. 20, *p* 1) has a simple, compressed, conical crown, thickest behind, and has two fangs; it is further removed from the second in the *Sus larvatus* than in the *Sus scrofa*. The second premolar (fig. 20, *p* 2) has a broader crown with a hind-lobe, having a depression on its inner surface, and each fang begins to be subdivided. The third premolar (fig. 20, *p* 3) has a similar but broader crown implanted by four fangs. The fourth premolar (fig. 20, *p* 4) has two principal tubercles and some irregular vertical pits on the inner half of the crown. The first true molar (*m* 1), when the permanent dentition is completed, exhibits the effects of its early development in a more marked degree than in most other Mammalia, and in the Wild Boar has its tubercles worn down, and a smooth field of dentine exposed, by the time the last molar has come into place; it originally bears four primary cones, with smaller subdivisions formed by the wrinkled enamel, and an anterior and posterior ridge. The four cones produced by the crucial impression, of which the transverse part is the deepest, are repeated on the second true molar (fig. 20, *m* 2) with more complex shallow divisions, and a larger tuberculate posterior ridge. The greater extent of the last molar (fig. 20, *m* 3) is chiefly produced by the development of the back ridge into a cluster of tubercles; the four primary cones being distinguishable on the anterior main body of the tooth. The crowns of the lower molars are very similar to those above but are rather narrower, and the outer and inner basal tubercles are much smaller, or are wanting; the grinding surface of the last is shown in fig. 122.

The first or deciduous dentition of the Hog consists of—

$$i \frac{3.3}{3.3}; c \frac{1.1}{1.1}; m \frac{3.3}{3.3} = 28, \text{ (fig. 17).}$$

The first milk-incisor above is large, oblique, trenchant, and with a depression on the inner surface of the crown; the second and third are pointed, the latter being as long as the milk-canine. The first and second incisors, below, are trenchant and oblique, and have the indentations and ridge slightly marked on the upper or inner side of the long and narrow crown; the third is pointed, and like a canine. The outer third milk-incisor in both jaws is more advanced in growth than the rest at birth. The canines are feeble, and have their normal direction in both jaws, the upper ones ascending according to the general type, which is not departed from until at a later period of life.

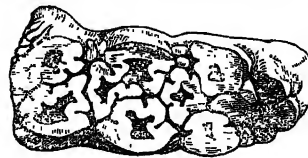

Fig. 122.
Last Lower Molar, Hog. Nat. size.

Teeth of Mammals.

Suidæ,
Hog-tribe.

Teeth of
Mammals.

The first deciduous molar is not succeeded by a premolar, but holds the place of such some time after the other deciduous molars are shed and succeeded by the premolars (*p* 2, 3, and 4). The last true molar (fig. 122) is remarkable for its large proportional size and complexity of grinding surface. By the time it is acquired and in use, the first true molar (*m* 1) is worn flat.

The Hog is the only existing hoofed genus that manifests, as regards number, the typical dentition displayed by the *Dichodon* in common with many other Eocene ungulate and ungulate Mammalia. The deviation in the Hog from this type is slight, being confined to the non-development of *p* 1, and the early reduction of the numerical formula by the loss of the small tooth (*d* 1, fig. 17 at the beginning of the molar series.

That the *Dichodon* belongs to the Artiodactyle series is inferred, notwithstanding the want of any direct evidence of the structure of its limbs, from the more simple form and structure of *p* 1, *p* 2, and *p* 3, as compared with the true molars, and from the symmetrical ruminating pattern of the grinding surface of the crown of the true molars.

From the true Ruminants the *Dichodon* differs in the development of the upper incisors and of *p* 1 in both jaws, which teeth are wanting in all the known existing species.

Such feeble traces of embryotic rudiments of these teeth as have been observed by Professor Goodsir and others, in the Cow and Sheep, and the more conspicuous germs of upper incisors, of which one pair is functionally developed, in the *Camelidae*, are phenomena that derive increased significance and interest from the fact of the functional development of the same teeth in Artiodactyle Ungulates of the Eocene period.

In the configuration of the true molars the *Dichodon* would seem to be more nearly allied to the Ruminant section of the *Artiodactyla*; in the number and kinds of its teeth it more resembles the Hog-tribe amongst the non-Ruminant section. The known facts of the deciduous dentition of the *Dichodon* supply an additional test of its affinities, owing to the marked differences, in the times and order of succession of the permanent teeth, between the Hog-tribe and the Ruminants, at least in the Ox and Sheep.

In these the last true molar cuts the gum before any of the premolars appear, and the canine teeth ("corner-nippers" of the veterinarians) are the last of the permanent teeth to come into place, their appearance marking the completion of the third year in the Sheep, and a somewhat later period in the Ox. In the Hog the canines appear before the premolars, and these are in place and use before the last molar is on a level with the rest of the grinders.

In the *Dichodon cuspidatus* the second true molar, in the upper jaw, is in place before any of the deciduous series of teeth have been shed; and it is coming into place, with the crown complete, before the pulps of the premolars have even begun to be calcified. The lower jaw of the sheep at from nine to twelve months would afford the nearest parallel amongst existing Artiodactyles to that of the immature *Dichodon* figured in pl. 4, fig. 2, vol. iv. of the *Quarterly Journal of the Geological Society*. But by the time the second true molar in the Sheep is as far advanced in development as in the *Dichodon* (fig. 2, loc. cit., p. 2, upper jaw) the first permanent incisor is in place, and the germs of the premolars in the cavities of reserve have calcified crowns.

The subjoined table indicates the several teeth by the symbols explained in the Section on the Homologies of the Teeth.¹

The necessity of exactness in the records of the age of the valuable breeds of domesticated cattle, exhibited in competition at agricultural meetings, has led to a greater accuracy in the statements of the periods of development of the different teeth in the Ox, Sheep, and Hog; and the results of the writer's observations, with those recorded by Bojanus, the learned veterinary professor at Wilna, and by Mr Simonds, the professor of cattle pathology in the Royal Veterinary College of London,² are averaged in the following

TABLE OF THE TIMES OF APPEARANCE OF THE PERMANENT TEETH IN THE OX, SHEEP, AND HOG.

Teeth of
Mammals.

The dentition of the Wart-hogs is reduced by the suppression of Phacocertain incisors, and of the first two premolars—the tooth-forming choerus. energy being, as it were, transferred to the last true molar, which is even more remarkable than in the common hog for its size and complexity in both jaws. Fig. 123 shows the condition of the upper

Fig. 123.]

Molar Series of adult Wart-hog (*Phacochoerus*). Nat. size.

molar series in a *Phacochoerus Eliani*, soon after the acquisition of *m* 3. The first true molar (*m* 1), in consequence of its being in place much earlier than the rest of the permanent series, as shown in fig. 124, is now almost worn out. The premolars (*p* 4 and *p* 3) continue

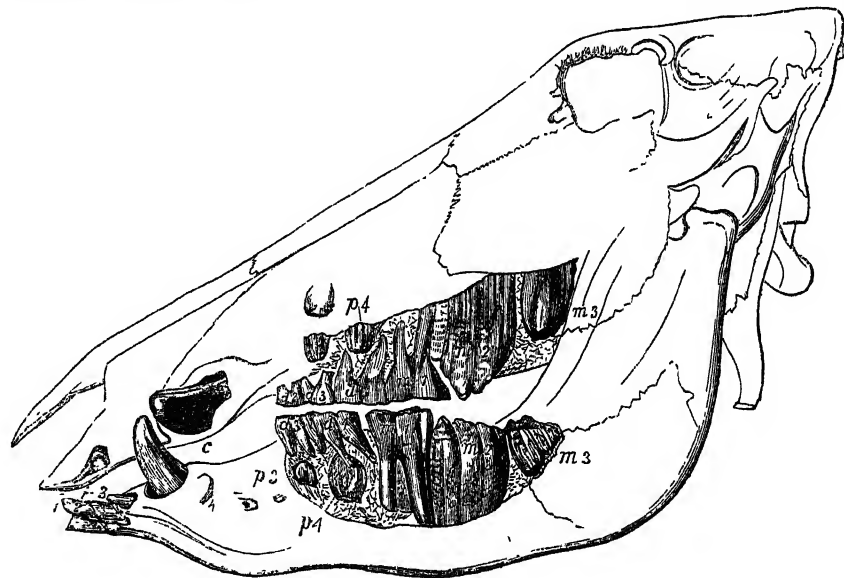

Fig. 124.

Dentition of a Young Wart-hog, *Phacochoerus*.

in use after *m* 1 is shed; and by the modifying growth of the jaw and the pressure on the grinders, they are brought into contact with *m* 2. The writer has seen instances in which *p* 4 has remained after *m* 2 has been shed, and when the molar series has been reduced to the teeth marked *p* 4 and *m* 3. This tooth (fig. 123, *m* 3)—the last true molar—is the most characteristic tooth of the *Phacochoerus*, and perhaps the most peculiar and complex tooth in the whole class of *Mammalia*. The surface of the crown presents three series of enamel islands, in the direction of the long axis of the grinding surface; the middle row, of eight or nine islands, is elliptic and simple; those of the other rows are in equal number, but are sometimes subdivided into smaller islands. These islands or lobes are the abraded ends of long and slender columns of dentine, encased by thick enamel, and the whole blended into a thick coherent crown by abundant cement,

¹ See also *Philosophical Transactions*, 1850, p. 481.

² *The Age of the Ox, Sheep, and Pig*, 8vo, 1854.

Teeth of Mammals. which fills up all the interspaces, and forms a thick exterior investment of the entire complex tooth.

The milk-molars are $\frac{2}{3}:\frac{2}{3}$ in number; but only the two last are succeeded by premolars (fig. 124, p 3 and p 4), although sometimes a small anterior milk-molar (*d* 2) is developed in the lower, as in the upper jaw. This interesting modification, as to order and number, in the change of the dentition, has thrown important light on the more anomalous dentition of the Elephant.

Hippopotamus.

The tendency to excessive and, as it may be termed, monstrous development which characterises the canine teeth in the typical *Suidæ*, affects both these and the incisors in the present remarkable genus, of which the *Hippopotamus* of the great rivers of Africa is now the sole existing representative.

The two median inferior incisive tusks are cylindrical, of great size and length, obliquely abraded at the upper and outer part of their extremity; the basal portion which is lodged in the deep alveolus is longitudinally grooved; the two outer incisors are likewise cylindrical and straight, are much smaller, and are worn towards the inner side of their point. The upper canines curve downwards and outwards, their exposed part is very short, and is worn obliquely at the forepart from above downwards and backwards; they are three-sided, with a wide and deep longitudinal groove behind. The lower canines (fig. 126) are extremely massive and large, curved in the arc of a circle, subtriangular, the angle rounded off between the two anterior sides, which are convex and thickly enamelled, the posterior side of the crown being almost wholly occupied by the oblique abraded surface opposed to that on the upper canine. The implanted base of each of these incisive and canine teeth is simple, and excavated for a large persistent matrix, contributing to their perennial growth by constantly reproducing the dental matter to replace the abraded extremities. The direction of the abraded surface is in part provided for by the partial disposition of the enamel. The molar series consists of—

$$\frac{4.4}{4.4}; m \frac{3.3}{3.3} = 28.$$

The first premolar has a simple subcompressed conical crown, and a single root; it rises early, and at some distance in advance of the second premolar, and is soon shed; the other premolars form a continuous series with the true molars in the existing species, but in the extinct *Hippopotamus major*, whose remains are found in the superficial deposits of this island and on the Continent, the second premolar is in advance of the third by an interval equal to its own breadth. This and the fourth premolar retain the simple conical form, but with increased size, and are impressed by one or two longitudinal grooves on the outer surface, which, when the crown is much worn, give a lobate character to the grinding surface. The true molars are primarily divided into two lobes or cones by a wide transverse valley, and each lobe is subdivided by a narrow antero-posterior cleft into two half cones, with their flat sides next each other; the convex side of each half cone is indented by two angular vertical notches,

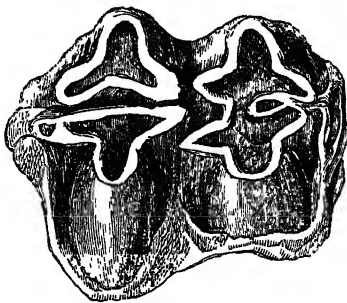

fig. 125

Molar Tooth, Hippopotamus

bounding a strong intermediate prominence.

When their summits begin to be abraded, each lobe or pair of demicones presents a double trefoil of enamel on the grinding surface, as shown in fig. 125; when attrition has proceeded to the base of the half cones, then the grinding surfaces of each lobe presents a quadrilobate figure. The crown of the last molar tooth of the lower jaw is lengthened out by a fifth cone, developed behind the two normal pairs of half cones, and smaller in all its dimensions.

The large tusks of the Hippopotamus exhibit the maximum of density in the chief component tissues. The enamel "strikes fire" with steel like flint. The compact dentine has a high commercial value, especially for the fabrication of artificial teeth. It differs from true ivory by showing, in transverse section, the simple concentric instead of the "engine-turned" or curvilinear decussating lines. In the ordinary-sized tusks the fine-tubed dentine, which forms the concentric-lined ivory, continues with little or no alteration of texture from the periphery to the pulp-cavity; but in very large and old tusks the apex of that cavity contains osteo-dentine, and that tissue is abundantly developed when the normal function of the dental pulp is disturbed by injury or disease. A very remarkable example of the inferior tusk of the Hippopotamus is figured in cut 126, exemplifying the subserviency of the osteo-dentine in the reparation of a complete fracture of a tooth.

The injury is indicated externally by a sudden transverse constriction.

Teeth of Mammals.

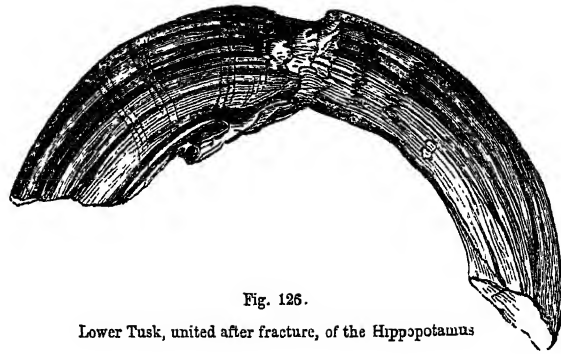

Fig. 126.

Lower Tusk, united after fracture, of the Hippopotamus

tion of the tusk (fig. 126), with an interruption in the enamel at that part, and irregular deposits of dentine both there and at the adjoining concavity of the tusk. A longitudinal section of the tusk showed the pulp-cavity obliterated at the fractured part, and for some distance below it, towards the base of the tusk, by a mass of osteo-dentine, deposited principally in the form of nodules closely impacted together, their convex sides projecting into the re-established pulp-cavity next the base, the general disposition of the osteo-dentine being very like that in the centre of the tooth of the Cachalot. The remains of the pulp-cavity in the protruded part, or crown of the tusk, were unusually conspicuous, in the form of a narrow canal near the concave side of the tusk, and opening like a fistula upon that surface just beyond the fracture. Another irregular slender canal extended transversely through part of the uniting substance, and opened upon the concave side of the tusk just below the preceding. From these appearances it may be concluded that the tusk, either by the action of a shot, or other violence, had been snapped across its implanted and hollow base, with probably also fracture and injury to the prominent socket; but that the broken portions being held together by their adhesion to the surrounding parts, inflammation of the pulp and capsule had ensued, ending in an altered mode of action in the calcifying processes, which produced the more vascular substance, which has exemplified its resemblance to true bone by effecting the union of the fracture.

The true natural affinities of the Hippopotamus are clearly manifested by the character of its deciduous dentition; and if this be compared with the dentition at a like immature period in other *Ungulata*, e. g., with that of the Horse tribe, it will be seen, by its closer correspondence with that of Artiodactyles, and more especially the Phacochere, that the Hippopotamus is essentially a gigantic Hog.

The formula of the teeth, which are shed and replaced, is—

$$\frac{2.2}{2.2}; c \frac{1.1}{1.1}; m \frac{3.3}{3.3} = 24.$$

If the small and simple tooth, which is developed anterior to the deciduous molars, and which has no successor, be regarded, from its early loss in the existing Hippopotamus, as the first of the deciduous series, we must then reckon with Cuvier four milk-molars on each side of both jaws.

The incisors in both jaws are simply conical and subequal, with an entire cap of enamel on the crown. The deciduous canines scarcely surpass them in size in the upper jaw, and not at all in the lower. Projecting forwards, here, from the angles of the broad and straight symphysis, they appear like an additional pair of incisors; and we have seen that the character of equality of development was retained by the ancient form of Hippopotamus with the more typical number of incisors, $\frac{3}{3}:\frac{3}{3}$, which formerly inhabited India.

The first true deciduous molar has a conical crown and two fangs in both jaws. That above has also a conical crown with one strong posterior and two anterior ridges. The second deciduous molar has a large trilobate crown, the first lobe small, with an anterior basal ridge; the second large, conical, with three longitudinal indentations; the third lobe still larger, and cleft into two half-cones by an antero-posterior fissure assuming the normal pattern of the true molars. The third deciduous molar above more closely resembles the ordinary upper true molar; but its second pair of demi-cones are relatively larger. In the lower jaw the last deciduous molar has a more complex crown than that of any other teeth of the permanent or deciduous dentition.¹ It has three pairs of demi-cones, progressively increasing in size, from before backwards, with an anterior and posterior basal ridge and tubercles. Like the last trilobate deciduous lower molar of the Hog, it increases in thickness posteriorly, instead of diminishing here, like the last true molar of the lower jaw of the adult Hippopotamus.

¹ This tooth is described as the first of four true molars by M. F. Cuvier, *Dents de Mammifères*, p. 207; but its true nature was recognised by Baron Cuvier. See *Ossemens Fossiles*, 4to, i. p. 289.

Teeth of
Mammals.
Equidae.
Perisso-
dactyla.

The Horse yields the first example of the dentition of the hoofed Quadrupeds with toes in uneven number, because it offers in this part of its organization some transitional features between those of the dental characters of the typical members of the artiodactyle and of those of the Perisso-dactyle *Ungulata*.

All the kinds of teeth are retained, in nearly normal numbers, in both jaws, and with almost as little unequal or excessive development as in the Anoplothere; but the prolongation of the slender

tooth, like the first. Two short folds partially detach a small accessory lobe at the posterior part of the crown.

The incisors (figs. 127, 128, *i*) are arranged close together in the arc of a circle at the extremity of both jaws. They are slightly curved, with long simple subtriangular fangs tapering to their extremity (fig. 131). The crowns are broad, thick, and short. The contour of the biting surface, before it is much worn, approaches an ellipse. These teeth, if found detached, recent or fossil, are distinguishable from those of the Ruminants by their greater curvature, and from those of all other animals by the fold of enamel (fig. 131, *c'*) which penetrates the body of the crown from its broad flat summit, like the inverted finger of a glove. When the tooth begins to be worn, the fold forms an island of enamel inclosed in a cavity, partly filled by cement and partly by the discoloured substances of the food; this is called by horse-dealers the "mark." In aged horses the incisors are worn down below the extent of the fold, and the mark disappears. The cavity is usually obliterated in the first, or mid-incisors at the sixth year, in the second incisors at the seventh year, and in the third or outer incisors, at the eighth year, in the lower jaw. It remains longer in those of the upper jaw, and in both the place of the mark continues for some years to be indicated by the dark-coloured cement.

Dentition of Lower Jaw, Horse.

some distance from the molars, and creates a long diastema, as in the Ruminants and Tapirs. The first deciduous molar (fig. 129, *d* 1)

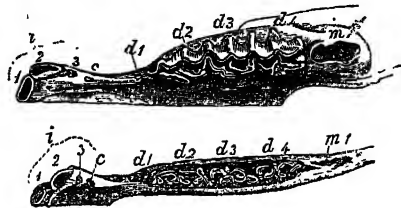

Fig. 129.
Deciduous Dentition, Horse.

is very minute, and is not succeeded, as in the Anoplothere, by a permanent premolar; yet, remaining longer in place than the larger deciduous molars behind, it represents the first premolar, and completes the typical number of that division of the grinding series. If the dental formula of the genus *Equus* be restricted to the functionally developed permanent teeth, it will be—

$$\begin{matrix} \frac{3.3}{3.3} & \frac{1.1}{1.1} & \frac{3.3}{3.3} & \frac{3.3}{3.3} \\ i & c & p & m \end{matrix} = 40.$$

The outer side of the upper molar of the Horse (*Equus Caballus*, fig. 130) is impressed, as in the Palæothere (fig. 117), by two wide longitudinal channels (fig. 130, *f, f*). The depression (*i*) is separated from the oblique valley (*e*); the depression (*g*) forms a crescentic island like *i*, when the crown begins to be worn away. There is a smaller depression (*h*) which indents the hinder side of the crown. An accessory lobe, apparently answering to that marked *m* in *Anoplotherium* (fig. 116), but more probably answering to the inner end of the lobe (*d*) in the Rhinoceros (fig. 132), is marked off by the anterior indentation

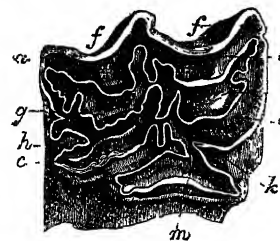

Fig. 130.
Upper Molar, Horse. Nat. size.

(*h*), and adds to the complexity of the crown, which, in the general aspect of the grinding surface, approaches in character to that of the Ruminants (fig. 120). In the lower jaw, the correspondence of type with that of the Rhinoceros is more obvious. The teeth here, as is usual in other quadrupeds, are narrower transversely than in the upper jaw; they are divided externally into two convex lobes (pl. 128, *m* 1 and 2) by a median longitudinal fissure, and on the inner side they present three principal unequal convex ridges, and an anterior and posterior narrower ridge; but the crown of the molar is penetrated from the inner side by deeper and more complex folds than in the Rhinoceros or Palæothere. The anterior one, between the narrow ridge and the first principal internal column, expands into a sub-crescentic fold; the second is a short, simple fold, and terminates opposite that which penetrates the tooth from the outer side; the third inner fold expands in the posterior lobe of the

The canines (figs. 127 and 128, *c*) are small in the stallion, less in the gelding, and rudimentary in the mare. The unworn crown is remarkable for the folding in of the anterior and posterior margins of enamel, which here includes an extremely thin layer of dentine. The upper canine (fig. 127, *c*) is situated in the middle of the long interspace between the incisors and molars. The lower canine (fig. 128, *c*) is close to the outer incisor, as in the Ruminants, but is better distinguished by its cuspidate form. The antetype, or representative of the first premolar (fig. 129, *d* 1), is a very small and simple rudiment, and is soon shed. The three normal premolars (figs. 127, 128, *p* 2, 3, and 4) are as large and complex as the true molars (figs. 127, 128, *m* 1, 2, 3). The anterior one (*p* 2) is usually the largest of the series in the upper jaw, the anterior lobe extending forwards into an obtuse angle.

The most obvious character by which the horse's molars may be distinguished from the complex teeth of other *Herbivora* corresponding with them in size, is the great length of the tooth before it divides into fangs. This division, indeed, does not begin to take place until much of the crown has been worn away; and thus, except in old horses, a considerable portion of the whole of the molar is implanted in the socket by an undivided base. This is slightly curved in the upper molars.

The following is the average course of development and succession of the teeth in the *Equus Caballus*.—The summits of the first functional deciduous molar (fig. 129, *d* 2, "first grinder" of veterinary authors) are usually apparent at birth; the succeeding grinder (*d* 3) sometimes rises a day or two later, sometimes together with the first. Their appearance is speedily followed by that of the first deciduous incisor (fig. 129, *i* 1, "centre nipper" of veterinarians) which usually cuts the gum between the third and sixth days. The second deciduous incisor (fig. 129, *i* 2) appears between the twentieth and fortieth days, and about this time the rudimentary grinder (*d* 1) comes into place, and the last deciduous molar (*d* 4) begins to cut the gum. About the sixth month the inferior lateral or third incisors (fig. 129, *i* 3), with the deciduous canine (*c*), make their appearance. The minute canine is shed about the time that the contiguous incisor is in place, and is not retained beyond the first year. The upper deciduous canine is shed in the course of the second year. The appearance of the third deciduous incisors or "corner nipper" completes the stage of dentition called the "colt's mouth" by veterinary authors. The first true molar (*m* 1) appears between the eleventh and thirteenth months. The second molar (*m* 2) follows before the twentieth month. The first functional premolar (*p* 2) displaces the deciduous molar (*d* 2) at from two years to two years and a half old. The first permanent incisor (figs. 127 and 128, *i* 1) protrudes from the gum at between two years and a half and three years. At the same period the second, or penultimate premolar (ib. *p* 3), pushes out the penultimate milk-molar (fig. 129, *d* 3), and the penultimate true molar (*m* 2) comes into place. The last premolar (*p* 4) displaces the last deciduous molar at between three years and a half and four years; the appearance above the gum of the last true molar (*m* 3) is usually somewhat earlier. The second incisor (*i* 2) pushes out its deciduous predecessor about the same period. The permanent canine or "tusk" (*c*) next follows; its appearance indicates the age of four years, but it sometimes comes earlier. The third, or outer incisor (fig. 128, *i* 3), pushes out the deciduous incisor (ib. *i* 3 *d*) about the fifth year, but is

Teeth of
Mammals.

Teeth of Mammals. seldom in full place before the horse is five years and a half old; the last premolar is then usually on a level with the other grinders. Upon the rising of the third permanent incisor, or "corner nipper" of the veterinarians, the "colt" becomes a "horse," and the "filly" a "mare," in the language of the horse-dealers; after the disappearance of the "mark" in the incisors, at the eighth or ninth year, the horse becomes "aged."

Rhinoceros. The modifications which the upper molars of the rhinoceros present, as compared with those of its antetype, the *Palæotherium*, will be readily understood by comparing fig. 117 with fig. 132, and are

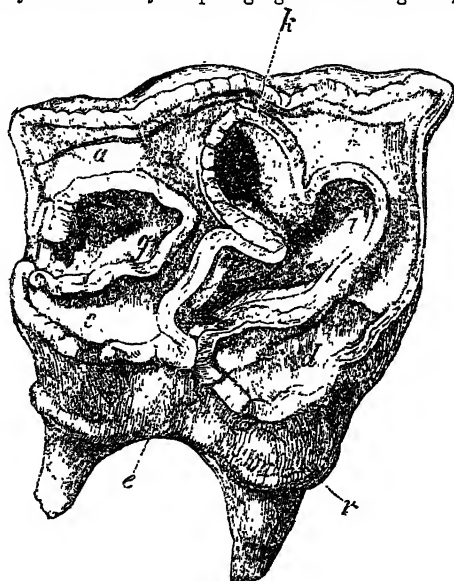

Fig. 132.
Upper Molar, Rhinoceros. Nat. size.

as follows:—The concavities (*f f*) on the outer side of the crown, in fig. 117, are almost levelled, and from one of them a slight convexity projects, in some species of Rhinoceros, giving a gently undulated surface on that side of the crown. The valley (*e*) is more expanded at its termination (*i*), and in some species bifurcates and deepens, so that one branch may form an insulated circle of enamel when the crown is worn. The posterior valley (*g*) is usually deeper and more extended. The ordinary lobes (*a, b, c, d*) are very similar, and produce, by the confluence of *a* with *c*, and of *b* with *d*, the two oblique tracts of dentine which are more decidedly established as transverse ridges in the Lophiodont or Tapiroid group. A basal ridge (*r*) girds more or less completely the inner and the fore and hind parts of the base of the crown.

The formula of the functional molar series is—

$$p \frac{4.4}{4.4}; m \frac{3.3}{3.3} = 28.$$

There are no canines. As to the incisors, the species vary, not only in regard to their form and proportions, but also their existence; and in the varieties of these teeth we may discern the same inverse relation to the development of the horns which is manifested by the canines of the Ruminants. Thus, the two-horned Rhinoceroses of Africa, which are remarkable for the great length of one (*Rh. bicornis*, *Rh. simus*) or both (*Rh. Keitloa*) of the nasal weapons, have no incisors in their adult dentition, neither had that great extinct two-horned species (*Rh. tichorinus*), the prodigious development of whose horns is indicated by the singular modifications of the vomerine, nasal, and pre-maxillary bones, in relation to the firm support of those weapons. The Sumatran bicorn Rhinoceros combines, with comparatively small horns, moderately-developed incisors in both jaws; and the same teeth are present in the nearly allied extinct two-horned Rhinoceros, called, after its discoverer, *Schleiermacheri*. The incisors are developed in both the existing Unicorn Rhinoceroses, (*Rh. Indicus* and *Rh. Sondaicus*), but they attain their largest dimensions in the singular extinct hornless species, the *Rhinoceros incisivus* of Cuvier, which makes the transition to the extinct genus *Palæotherium*, and forms the type of the aberrant subgenus *Acerotherium* of Dr Kaup.

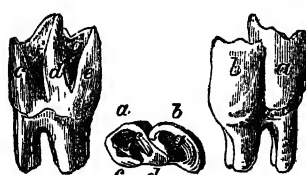

Fig. 133.
Lower Molar, Rhinoceros.

pearance shewn in the middle of the three figures in cut 133, from a molar of the right ramus of the lower jaw. The figure

opposite the right hand shews the outer side, that opposite the left hand the inner side. In each figure, *a d* is the anterior lobe, **Teeth of Mammals.**

Fig. 134.
Deciduous and Permanent Teeth, Hyrax. Nat. size.

b e the posterior lobe; *c* is the antero-internal border, and *d* the postero-internal border of the anterior lobe; *e* is the postero-internal border of the posterior lobe; *f* is the concavity of the anterior, *g* that of the posterior lobe. The above structure characterises the last two premolars and all the true molars of the lower jaw of the Rhinoceros, the ultimate one not being characterised, as in the *Palæotherium*, by an accessory lobe.

The deciduous molars of the Rhinoceros are, in number as well as in shape, closely similar to those in the diminutive, hornless, hairy, rhinoceros-like quadruped, called *Hyrax*, which bears the same relation to the great Rhinoceros as the small existing Sloth does to the extinct Megatherium. The change of dentition of the *Rhinocerotidae* is, therefore, here illustrated by the young *Hyrax capensis* (fig. 134).

The law of development, so instructive and constant in the placental *Diphyodonts*, is well illustrated in this species. The four premolars (*p 1, 2, 3, 4*) are exposed above the four deciduous molars (*d 1, 2, 3, 4*), which they push out; the first true molar (*m 1*) is in place; the second (*m 2*) and third (*m 3*) molars are in different states of forwardness. The first premolar differs from the rest only by a graduated inferiority of size, which, in the last premolar (*p 4*), ceases to be a distinction between it and the true molars.

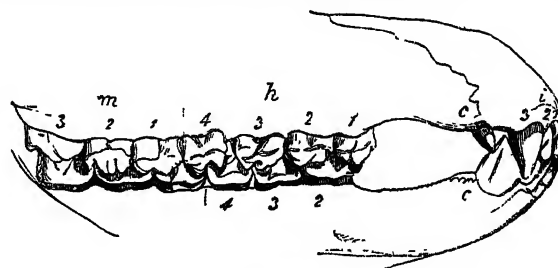

Fig. 135

Dentition of the Tapir.

The dental formula of the Tapir is—

$$i \frac{3.3}{3.3}; c \frac{1.1}{1.1}; p \frac{4.4}{4.4}; m \frac{8.3}{8.3} = 42 \text{ (fig. 135).}$$

Tapirus.

The median incisors above (*i 1, 2, 3*) have a broad trenchant crown, separated by a transverse channel from a large basal ridge; the wedge-shaped crowns of the opposite pair below fit into the channel, and have no basal ridge; the outer incisors above (*i 3*) are very large and like canines; those below are unusually small. The canines (fig. 135, *c*) have crowns much shorter than their roots, and not projecting, like tusks, beyond the lips; they are pointed, with an outer convex, separated by sharp edges from an inner, less convex, surface. The lower canines form part of the same semicircular series with the incisors; the upper ones project close to the intermaxillary suture, separated from the incisors by a short space for the reception of the crown of the lower canine. The first three premolars above (*p 1, 2, 3*) have the outer part of the crown composed of two half cones, the posterior one having a basal ridge; the anterior basal ridge rises into a small cusp in the second premolar, which increases in size in the third and fourth; in this tooth (*p 4*) the transverse depression divides at the base of the anterior and outer demicone, and the posterior division is continued into the interspace of the two demicones; these, therefore, now become in *m 1* and *2* the outer ends of the two transverse wedge-shaped eminences, giving their summits a curve whose concavity is turned backwards; the last molar (*m 3*) may be known by the shorter and more curved posterior eminence. In the dentition of the lower jaw (fig. 136) the double transverse ridged type of tooth, which has been before described in the Kangaroo,

Fig. 136.

Molar Series, Lower Jaw, Tapir.

Teeth of
Mammals.

Diprotodon, and Manatee, prevails throughout the molar series, the anterior talon being most produced and compressed in the first tooth (*p* 2).

The most extraordinary of extinct Pachyderms is that which Cuvier regarded as a gigantic Tapir, on account of the character of the molar teeth (see the lower fig. in cut 137); but which subsequent

verse ridges, and an anterior and posterior talon, the latter being more developed than in the corresponding molars of the upper jaw.

As the three-ridged or first true molar tooth is the first of the permanent series which comes into place, its crown, conformably with the general law, exhibits most abrasion.

The generic peculiarity of the *Dinotherium* is most strongly manifested in its tusks. These tusks (fig. 137) are two in number, implanted in the prolonged and deflected symphysis of the lower jaw, in close contiguity with each other, and having their exerted crown directed downwards and bent backwards, gradually decreasing to the pointed extremity. Each tusk has a slight longitudinal depression on its outer side; the long implanted base is excavated by a wide and deep conical pulp-cavity, like the tusks of the Mastodon and Elephant.

In jaws with molar teeth of equal size, the symphysis and its tusks offer two sizes; the larger ones, which have been found four feet in length, with tusks of two feet, may be attributed to the male *Dinotherium*; the smaller specimens, with tusks of half size, to the female. The ivory of these tusks presents the fine concentric structure of those of the Hippopotamus, not the decussating curvilinear character which characterises the ivory of the Elephant and Mastodon. No corresponding tusks, nor the germs of such, have yet been discovered in the upper jaw of the *Dinotherium*.

No family of Mammalian quadrupeds has suffered more from the destructive operations of time than that which is characterised by the gigantic size of the individuals composing it, and their peculiar endowment of a long and prehensile proboscis. The Elephants of Africa, India, Ceylon, and Sumatra, represent the proboscidean type of the hoofed series of mammals at the present day; but much more numerous species of as huge proboscideans formerly existed, dispersed over a wider geographical range, and in which the Elephantine dentition was reduced by gradational series of modifications almost to the comparative simplicity of that of the *Dinotherium* and Tapir.

The name *Mastodon* was applied by Cuvier to certain species, which, being at the Tapiroid or *Dinotherian* extremity of the proboscidean series, manifested modifications of the teeth most meriting to be held generically distinct from those of the existing Elephants. The grinding surface of the molars (fig. 138), instead of being cleft into numerous thin plates, was divided into wedge-shaped transverse ridges, and the summits of these were subdivided into smaller cones, more or less resembling the teats of a cow, whence the generic name.¹ A more important modification appeared to distinguish the extinct genus, in respect of the structure of the molar teeth; the dentine, or

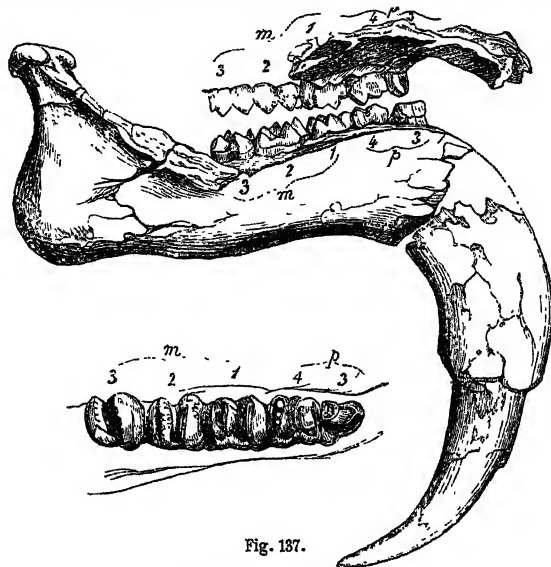

Teeth of
Mammals.

Fig. 137.
Dentition of *Dinotherium*

discovery of the cranium, and the enormous tusks of the lower jaw (fig. 137), has proved to be a genus connecting the tapiroid with the proboscidean families of Perissodactyla.

The permanent dentition of the genus *Dinotherium* is—

$$\begin{matrix} i & 00 \\ & 11 \end{matrix} ; \begin{matrix} c & 00 \\ & 00 \end{matrix} ; \begin{matrix} p & 22 \\ & 22 \end{matrix} ; \begin{matrix} m & 33 \\ & 22 \end{matrix} = 22.$$

The two deciduous molars *in situ* on each side of the fragment of the upper jaw of the young *Dinotherium*, which Professor Kaup has figured in Tab. I of his *Ossemens Fossiles de Darmstadt*, answer to the third and fourth of the typical series. The crown of the anterior milk-molar supports two transverse ridges with an anterior and posterior basal ridge; its contour is almost square; the last milk-molar has a greater antero-posterior extent, and supports three transverse eminences with an anterior and posterior basal ridge, the anterior ridge being developed into a pointed tubercle at its outer end. The two premolars (fig. 137, *p* 3 and 4) conform to the general rule in being more simple than the teeth which they displace and succeed. The first upper premolar (*p* 3) supports a longitudinal ridge on the outer side of the crown, and two mamilloid tubercles, with confluent bases along the inner side of the crown, which is surrounded, except at its outer part, by a basal ridge. The unworn summits of both the ridge and tubercles are divided into smaller tubercles by a series of notches. The crown of the second premolar (*p* 4) supports four tubercles, the outer ridge being deeply cleft, and the two anterior tubercles are united by a continuous ridge, which converts them into a transverse eminence, like those which characterise the true molar teeth. The transverse diameter of the second premolar exceeds the antero-posterior one, the proportions being the reverse of those of the deciduous molar, which it displaces. The first true molar (*m* 1) repeats the structure of the hindmost deciduous molar, its crown having a disproportionate antero-posterior extent, and supporting three transverse eminences, with an anterior, posterior, and internal basal ridge. The *Dinotherium* resumes the Tapiroid character, and differs essentially from the Mastodon, inasmuch as the posterior molars (*m* 2 and 3), instead of having an increased antero-posterior extent and more complex crowns, increase only in thickness, and support two instead of three transverse eminences; they have also an anterior and a posterior basal ridge. In the lower jaw the first premolar (*p* 3) is implanted, like that above, by two fangs; but it has a smaller and simpler crown, which is narrower in proportion to its antero-posterior extent, and is almost entirely occupied by the antero-posterior ridge, only the posterior of the two inner tubercles being developed; thus the crown presents more of a trenchant than of a grinding character; the second premolar (*p* 4) supports two transverse ridges. The third of the permanent series, which is the first true molar (*m* 1), has three transverse ridges, like the one above, but is relatively narrower, the second (*m* 2) and third (*m* 3) true molars have each large square crowns, with two trans-

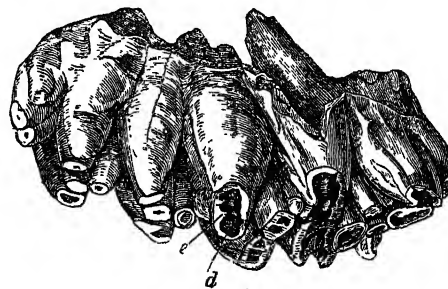

Fig. 138.

Upper Molar of Mastodon.

principal substance of the crown of the tooth (fig. 138, *d*) is covered by a thick coat of dense and brittle enamel (*e*); a thin coat of cement is continued from the fangs upon the crown of the tooth, but this substance does not fill up the interspaces of the divisions of the crown, as in the Elephants (fig. 144, *c*). Such at least is the character of the molar teeth of the typical and first-discovered species of Mastodon, which Cuvier has termed *Mastodon giganteus* and *Mastodon angustidens* (fig. 138). Fossil remains of proboscideans have subsequently been found principally in the tertiary deposits of tropical Asia, in which the number and depth of the clefts of the crown of the molar teeth, and the thickness of the intervening cement, are so much increased as to establish transitional characters between the lamello-tuberculate teeth of the Elephants and the mammilated molars of the typical Mastodons, showing that the characters deducible from the molar teeth are rather the distinguishing marks of species than of genera in the present family of mammalian quadrupeds.

The dentition of this family may be expressed by the formula—

$$d \begin{matrix} i & 11 \\ & 11 \end{matrix} ; \begin{matrix} i & 11 \\ & 11 \end{matrix} ; \begin{matrix} c & 00 \\ & 00 \end{matrix} ; \begin{matrix} m & 33 \\ & 33 \end{matrix} ; \begin{matrix} p & 11 \\ & 11 \end{matrix} ; \begin{matrix} m & 33 \\ & 33 \end{matrix} = 34;$$

that is to say, in the proboscideans in which the dentition most nearly approached to the typical one, thirty-four teeth were developed,

¹ *μαστος*, a nipple; *οδον*, a tooth.

Teeth of
Mammals.

as follows:—In the upper jaw two

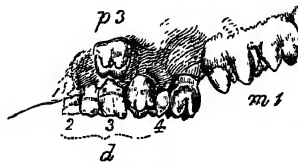

Fig. 139.

Deciduous dentition, young *Mastodon longirostris*.

animal (*Mastodon longirostris*, Kaup; *Mastodon angustidens*, in part, Cuvier) which exhibited the above instructive dentition of the Proboscidian family, once roamed over the part of the earth now forming England, France, Italy, and Germany. The first steps in our knowledge of its dentition were made by Cuvier, who called it the narrow-toothed *Mastodon* "*Mastodon à dents étroites*," or *Mastodon angustidens*. This name was suggested by the less breadth of the grinding surface

deciduous incisors, followed by two permanent incisors developed as tusks; six deciduous molars, (three on each side, *d* 2, 3, 4, fig. 3 9; two premolars (one on each side, *p* 3, fig. 139), and six true molars (three on each side, *m* 1, 2, 3, figs. 139 and 140):—in the lower jaw, two incisors as tusks (uncertain whether preceded by deciduous tusks), deciduous molars, premolars, and molars, as in the upper jaw. The Elephantoid

todon angustidens (his *longirostris*), in which it is still concealed in its formative cavity above the three-lobed deciduous tooth which it has replaced in Cuvier's specimen. The tooth next behind, which is the homologue of the last milk-molar (*d* 4, fig. 139) of the typical series, consists, in both the Dax and Eppelsheim specimens, of three principal ridges and a posterior bituberculate talon; this accessory portion being more developed in the Eppelsheim specimen. Whether such difference be valid for a specific distinction may be doubted; but that Cuvier assigned the name *angustidens* to a *Mastodon* with narrower molars than the *M. giganteus*, which had a quadri-tuberculate premolar, a penultimate molar of four principal divisions and a talon, and a last molar with five principal divisions and a talon, is certain. To that *Mastodon*, therefore, which has the same shaped and sized ultimate and penultimate true molars and premolar, the same name is here assigned.

The antepenultimate molar (fig. 139, *m* 1) consists of four ridges and a talon.

Three molars are developed anterior to this tooth; the first (fig. 3, *d* 2) is the smallest, with a subquadrate crown of two transverse ridges. The second molar (fig. 3, *d* 3), of twice the size of the first, has three ridges. The third molar (*d* 4), with an increase of one third the bulk of the former, has three ridges and a bituberculate talon, which in some specimens might almost be reckoned as a fourth ridge. The two-ridged premolar (*p* 3) above described, takes the place of the second of the above molars, after the first and second are shed. The above definition of the molar series applies to both upper and lower jaws, the cut (fig. 136), and the symbolic letters and numbers, preclude the necessity of verbal description.

From the analogy of the existing elephants, it may be inferred that the long tusks (fig. 137, *t*) supported by the premaxillaries, were preceded by a pair of small deciduous incisors. There is not such ground for concluding their existence in the mandible; but this jaw, at least in the male *Mastodon*, supported two incisive tusks, shorter and straighter than those above.

In the Proboscidian quadrupeds the molar teeth, progressively increasing in size, and most of them in complexity, follow each other from before backwards, at longer intervals than in other quadrupeds, and are never simultaneously in place. Not more than three are in use at any period on one side of either jaw; all the molars, save the penultimate (fig. 140, *m* 2) are shed by the time the crown of the last molar has cut the gum, and the dentition is finally reduced to *m* 3 on each side of both jaws, with commonly the loss of the inferior tusks, as in the old *Mastodon angustidens*, from the tertiary deposits of the Po, described and figured by Sismonda.³

The readiest and most intelligible key to the homologies of the above-described dentition, aberrant as regards the Mammalian type, but typical amongst the Proboscidian modifications, is that afforded by the Wart-hog (*Phacochoerus*). In fig. 122 the symbols are attached to the several teeth indicative of their homologies, as undoubtedly determined by comparison with the Hogs that retain the typical dentition.

The Wart-hog, moreover, is the hoofed animal that makes the nearest approach to the Elephant in the complex structure of the molars, in their progressive increase of size and complexity, in the early loss of the anterior molars, and the ultimate reduction of the series to the last large and complex one (*m* 3).

In *Phacochoerus* (fig. 122) only the last two premolars (*p* 3 and 4) are developed; in *Mastodon* (fig. 136): only the penultimate one (*p* 3); in *Elephas* proper, even this tooth becomes obsolete, and the guide to the deciduous molars is restricted to the homology of the true molars (*m* 1, *m* 2, and *m* 3), with the answerable teeth in *Mastodon* and *Phacochoerus*.⁴

As to the teeth anterior to the molar series, some might be tempted to regard the tusks of the Proboscidian as the homologue of the tusk-like canines of the boar tribe, advanced to the position of the incisors, which are in that view wholly wanting. But the numerous instances in which in *Herbivora*, the canines are obsolete whilst the incisors are retained, and the true incisive nature of the premaxillary tusk-like teeth in the Rodents, show the determination of the premaxillary and symphyseal tusks of the Proboscidians, as incisors, to be the sounder conclusion.

The dentition of the genus *Elephas*, the sole existing modification Elephas. of the once numerous and various Proboscidian family, includes two long tusks, one in each of the premaxillary bones, and large and complex molars in both jaws. Of the latter there is never more than one wholly, or two partially, in place and use on each side at any given time, the series continually being in progress of formation

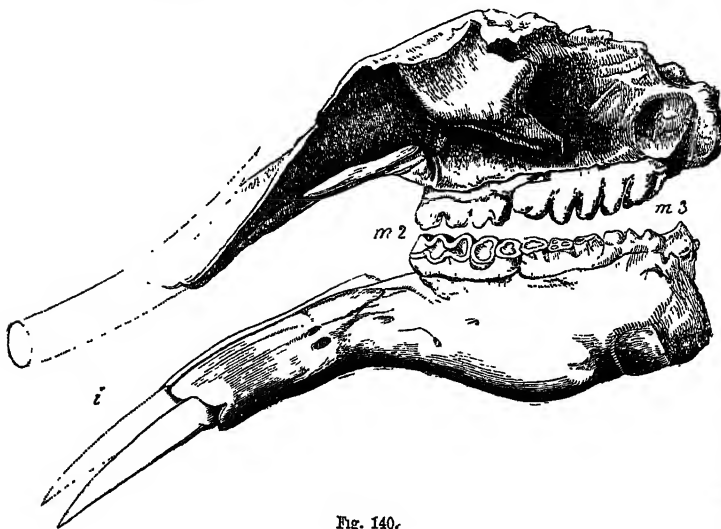

Fig. 140.

Dentition of old *Mastodon longirostris*.

of the teeth as compared with those of a previously described species of *Mastodon* from North America, called the *Mast. giganteus* or *M. Ohioticus*. Cuvier describes and figures a last molar, upper jaw, from Trévoux, consisting, as in the specimen from Norfolk Crag (fig. 138), and as in that from Eppelsheim (fig. 140, *m* 3), of five transverse ridges, with a front and back talon or subsidiary ridge. The latter is the largest, and subdivided into teat-shaped tubercles, so as almost to merit the name of a sixth division of the tooth. The principal ridges are divided into two chief or primary tubercles, with secondary tubercles in the interspace; the chief tubercles are more or less deeply grooved lengthwise, or cleft at top, so that mastication wore them down to small circles of dentine surrounded by a thick border of enamel, and further attrition reduced these to a trilobed or trefoil form.

The last lower molar of the *Mast. angustidens* from La Rochetta di Tanaro,¹ exhibits the same five principal transverse ridges and the hinder one, as in the corresponding tooth in the Eppelsheim *Mastodon* (fig. 140, *m* 3), and being the first of the series of narrow mastodontoid teeth to which Cuvier applied the name *angustidens*, it may be regarded as the type of that species. The characteristic premolar of the *Mast. angustidens*, with a quadrate crown of two ridges, each cleft into two tubercles (fig. 139, *p* 3), is figured by Cuvier, in Op. cit. pl. i., fig. 3, and again, *in situ*, with the last deciduous molar (*d* 4) in a portion of the upper jaw of the *Mastodon angustidens* from Dax (ib. pl. iii., fig. 2). The nature of this quadrituberculate tooth as a premolar, *i. e.*, as a tooth which displaced and succeeded an earlier or deciduous tooth in the vertical direction, was recognised by Cuvier. "Je crois encore qu'on peut en conclure que la dent antérieure était susceptible de remplacement de haut ou bas, comme dans l'hippopotame: ma raison est, que cette petite dent de Dax n'est pas encore usée et qu'il faut qu'elle soit venue après la grande qui l'est."² Dr Kaup has described and figured the same premolar in the upper jaw of a younger individual of the *Mas-*

Teeth of
Mammals.

and destruction, of shedding and replacement; and, in the Elephants, all the grinders succeed one another, like true molars, horizontally, from behind forwards. The total number of teeth developed in the Elephant appears to be—

$$d: \frac{1.1}{0.0} : i: \frac{1.1}{0.0} : dm: \frac{3.3}{3.3} : m: \frac{3.3}{3.3} = 28.$$

The two large permanent tusks are preceded by two small deciduous ones, and the number of molar teeth which follow one another on each side of both jaws is certainly not less than six, of which the last three answer to the last three in the Mastodon, and to the true molars, *m* 1, 2 and 3, of other diphyodont placental Mammals. The writer has shewn in his *Odontography*, that "the deciduous tusk makes its appearance beyond the gum between the fifth and seventh months. It rarely exceeds two inches in length, and is about a third of an inch in diameter at its thickest, where it protrudes from the socket. The fang is solidified, and contracts to its termination, which is commonly a little bent, and is considerably absorbed by the time the tooth is shed, which takes place between the first and second year." "The socket of the permanent tusk in a new-born Elephant is a round cell about three inches in diameter, situated on the inner and posterior side of the aperture of the temporary socket." The permanent tusks cut the gum when about an inch in length, a month or two usually after the milk-tusks are shed. At this period, according to Mr Corse,¹ the permanent tusks are "black and ragged at the ends; when they become longer, and project beyond the lip, they soon are worn smooth by the motion and friction of the trunk." Their widely-open base is fixed upon a conical pulp, which, with the capsule surrounding the base of the tusk and the socket, continues to increase in size and depth, obliterating all vestiges of that of the deciduous tusk, and finally extending its base close to the nasal aperture. The ivory of the tusk is formed by successive calcification of layers of the pulp, in contact with the inner surface of the pulp-cavity; and, being subject to no habitual attrition from an opposed tooth, but being worn only by the occasional uses to which it is applied, it arrives at an extraordinary length. It follows the curve originally impressed upon it by the form of the socket, and gradually widens from the projecting apex to that part which was formed when the matrix and the socket had reached their full size.

These incisive teeth of the Elephant not only surpass other teeth in size as belonging to a quadruped so enormous, but they are the largest of all teeth in proportion to the size of the body; representing, in a natural state, those monstrous incisors of the Rodents (fig. 92), which are the result of accidental suppression of the wearing force of the opposite teeth.

The tusks of the Elephant, like those of the Mastodon, consist chiefly of that modification of dentine which is called "ivory," and which shows, on transverse fractures or sections, striæ proceeding in the arc of a circle from the centre to the circumference in opposite directions, and forming, by their decussations, curvilinear lozenges. This character is peculiar to the tusks of the Proboscidean Pachyderms, and is characteristic of true ivory. In the Indian Elephant there is a well-marked sexual difference in the growth of the tusks. They are always short and straight in the female, and less deeply implanted than in the male; she thus retaining, as usual, more of the characters of the immature state. In the male they have been known to acquire a length of nine feet, with a basal diameter of eight inches, and to weigh one hundred and fifty pounds; but these dimensions are rare in the Asiatic species.

Mr Corse, speaking of the variety of Indian Elephant, called "Dauntelah" from its large tusks, which project almost horizontally with a slight curve upwards and outwards, says: "The largest I have known in Bengal did not exceed seventy-two pounds avoirdupois; at Tipurah they seldom exceed fifty pounds." There are varieties of the Dauntelah, in which the large tusks of the male are nearly or quite straight; and in a more marked breed called "Mooknah" the tusks are much smaller, are straight, and point directly downwards. These ascertained varieties in an existing species ought to weigh with the observers of analogous varieties in the teeth of fossil Proboscideans, before they pronounce definitely on their value as characters of distinct species. More anomalous varieties occasionally present themselves in the African Elephant, as when one tusk is horizontal, the other vertical, or when, from some distortion of the alveolus, a spiral direction is impressed upon the growth of the tusk, as in that specimen figured by Grew in the "Rarities of Gresham

College," tab. 4, and which is now in the Museum of the Royal College of Surgeons, London.² The tusk of the Elephant is slightly movable in its socket, and readily receives a new direction of growth from habitual pressure; this often causes distorted tusks in captive Elephants; and Cuvier relates the mode in which advantage was taken of the same impressibility in order to rectify the growth of such tusks in an Elephant kept at the Garden of Plants in Paris.

The tusks of the extinct *Elephas primigenius*, or mammoth, have a bolder and more extensive curvature than those of the *Elephas indicus*; some have been found which describe a circle, but the curve being oblique, they thus clear the head, and point outwards, downwards, and backwards. The numerous fossil tusks of the Mammoth which have been discovered and recorded, may be ranged under two averages of size—the larger ones at nine feet and a half, the smaller at five feet and a half in length. The writer has elsewhere³ assigned reasons for the probability of the latter belonging to the female Mammoth, which must accordingly have differed from the existing Elephant of India, and have more resembled that of Africa in the development of her tusks, yet manifesting an intermediate character by their smaller size. Of the tusks which are referable to the male Mammoth, one from the newer tertiary deposits in Essex measured nine feet ten inches along the outer curve, and two feet five inches in circumference at its thickest part; another from Eschscholtz Bay was nine feet two inches in length, and two feet one and a half inches in circumference, and weighed one hundred and sixty pounds. A specimen, dredged up off Dungeness, measured eleven feet in length. In several of the instances of Mammoth's tusks from British strata, the ivory has been so little altered as to be fit for the purposes of manufacture; and the tusks of the Mammoth, which are still better preserved in the frozen drift of Siberia, have long been collected in great numbers as articles of commerce.⁴

In a specimen of the extinct Indian Elephant (*Elephas ganesa*, Fr. and C.) preserved in the British Museum, the tusks are ten feet six inches in length, and in consequence of their small amount of curvature, they project eight feet five inches in front of the head. Their apparent disproportion to the size of the skull is truly extraordinary, and exemplifies the maximization of dental development. Cuvier⁵ states that the Elephant of Africa, at least in certain localities, has large tusks in both sexes, and that the female of this species, which lived seventeen years in the menagerie of Louis XIV., had larger tusks than those in any Indian Elephant, male or female, of the same size which he had seen. The ivory of the tusks of the African Elephant is most esteemed by the manufacturer for its density and whiteness.

The molar teeth of the Elephant are remarkable for their great size, even in relation to the bulk of the animal, and for the extreme complexity of their structure (fig. 141). The crown, of which a great proportion is buried in the socket, and very little more than the grinding surface appears above the gum, is deeply divided into a number of transverse perpendicular plates, consisting each of a body of dentine (*d*), coated by a layer of enamel (*e*), and this again by the less dense bone-like substance (*c*) which fills the interspaces of the enamelled plates, and here more especially merits the name of "cement," since it binds together the several divisions of the crown, as at *c*, before they are fully formed and united by the confluence of their bases into a common body of dentine. As the growth of each plate begins at the summit, they remain detached, and like so many separate teeth or denticles, as at the back part of fig. 141, until their base is completed, when it becomes blended with the bases of contiguous plates to form the common body of the crown of the complex tooth, from which the roots are next developed. The plates of the molar teeth of the Siberian Mammoth (*Elephas primigenius*, fig. 142) are thinner in proportion to their breadth, and more numerous in proportion to the size of the crown, than in the existing species of Asiatic Elephant (fig. 143).

In the African Elephant (fig. 144), on the other hand, the lamellar divisions of the crown are fewer and thicker, and they expand from the margins to the centre of the tooth, yielding a lozenge form when cut or worn transversely, as in mastication.

The horizontal as well as vertical course of development of the Elephant's grinder is well illustrated by the molar, the last of the lower jaw (fig. 141). The separate digital processes of the posterior plates are still distinct, and adhere only by the remaining cement. A little in advance we see them united to form the transverse plate

Teeth of
Mammals.

¹ See Mr Corse's Memoir on the Teeth of the Elephant, in the *Philosophical Transactions*, 1799, p. 211. A good figure of the deciduous tusk is given in plate 5.

² Osteol. Series, No. 2757. The writer is indebted to the distinguished traveller, Dr Livingstone, for a similar tusk of an African Elephant, from the Zambesi district.

³ *History of British Fossil Mammals*, 8vo, p. 247.

⁴ In the account of the Mammoth's bones and teeth of Siberia, published in the *Philosophical Transactions* for 1737 (No. 446), tusks are cited which weighed two hundred pounds each, and "are used as ivory to make combs, boxes, and such other things; being little more brittle and easily turning yellow by weather and heat." From that time to the present there has been no intermission in the supply of ivory furnished by the tusks of the extinct Elephants of a former world.

⁵ *Loc. cit.* p. 55.

Teeth of Mammals. (*g, g*), and at the opposite extremity of the tooth the common base of dentine (*d*) is exposed, by which the plates are finally blended into

one individual complex grinder.¹ This never takes place simultaneously along the whole extent of the tooth in the Indian Elephant.

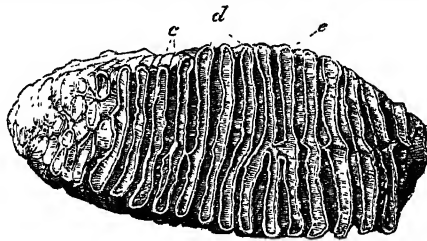

Fig. 142.

Upper Grinder of the Mammoth, (*Elephas primigenius*).

The African species manifests a closer affinity to the Mastodon by the basal confluence of the plates before the anterior ones are worn out.

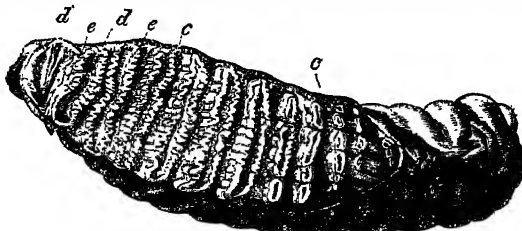

Fig. 143.

Upper Molar, Asiatic Elephant.

The formation of each grinder begins with the summits of the anterior plate, and the rest are completed in succession; the tooth is

Fig. 144.

Upper Molar, African Elephant.

gradually advanced in position as its growth proceeds, and in the existing Indian Elephant, the anterior plates are brought into use before the posterior ones are formed. When the complex molar cuts the gum the cement is first rubbed off the digital summits, then their enamel cap is worn away, and the central dentine comes

and polished field of dentine, with perhaps a few remnants of the bottom of the enamel folds at its hinder part.

When the complete molar has been thus worn down to a uniform surface, it becomes useless as an instrument for grinding the coarse vegetable substances on which the Elephant subsists; it is attacked by the absorbent action, and the wasted portion of the molar is finally shed. The grinding teeth of the Elephant progressively increase in size and in the number of lamellar divisions from the first to the last, and as the rate of increase in both respects is nearly identical in both jaws, they are here described as they appear in the lower one (fig. 141).

The first molar, which cuts the gum in the course of the second Succession. week after birth, has a subcompressed crown nine-lines in antero-posterior diameter, divided by three transverse clefts into four plates, the third being the broadest, and the tooth here measuring six lines across. The first and second plates have two mamilloid summits, the third and fourth have three or four such; there is a single and sometimes a double mamilloid summit at the fore and back part of the crown, and the base slightly contracts, and forms a neck as long as the enamelled crown, but of less breadth, and this divides into anterior and posterior long, subcylindrical, diverging, but mutually incurved fangs; the total length of this tooth is one inch and a half. The corresponding upper molar, which Mr Corse describes as cutting the gum a little earlier than the lower one, has the anterior process or mamilla, and the posterior talon, developed into a fifth plate, smaller than the fourth, with which its middle part is confluent; the neck of this tooth is shorter, and the two fangs are shorter, larger, and more compressed, than those of the lower first molar. This tooth is the homologue of the deciduous molar (fig. 139, *d* 2) in the Mastodon and other Ungulates; it is not a mere miniature of the great molars of the mature animal, but retains, agreeably with the period of life at which it is developed, a character much more nearly approaching that of the ordinary pachydermal molar, manifesting the adherence to the more general type by the minor complexity of the crown, and by the form and relative size of the fangs. In the transverse divisions of the crown we perceive the affinity to the Tapiroid type, the different links connecting which with the typical Elephants are supplied by the extinct Lophiodons, Dinotheriums, and Mastodons. The subdivision of the summits of the primary plates recalls also the character of the molars, especially the smaller ones, of the Phacochere in the Hog tribe. As the Elephant advances in age, the molars rapidly acquire their more special and complex character. The first molars are completely in place and in full use at three months, and are shed when the Elephant is about two years old.

The sudden increase and rapid development of the second molar answering to *d* 3 in fig. 139, may account for the non-existence of any vertical successor to the former tooth, or "premolar," in the Elephant. The eight or nine plates of the crown of this tooth are formed in the closed alveolus, behind the first molar, by the time this cuts the gum, and they are united with the body of the tooth, and most of them in use, when the first molar is shed. The average length of the second molar is two inches and a half, ranging from two inches to two inches and nine lines; the greatest breadth, which is behind the middle of the tooth, is from one inch to one inch three

¹ Some anatomists have described the divisions of the crown of the Elephant's grinder as so many "distinct teeth," and Mr Corse (loc. cit. p. 218), who first propounded this view, calls each complex grinder "a case of teeth," and states, "that these teeth are merely joined to each other by an intermediate softer substance acting like cement." But this statement applies only to the incompletely formed tooth; and the detached eminences of each individual plate, or of the crown of any complex tooth, at that stage of growth when they are held together only by the still uncalcified supporting matrix, might reasonably be regarded as so many distinct teeth.

Teeth of
Mammals.

lines. There are two roots; the cavity of the small anterior one expands in the crown, and is continued into that of the three anterior plates. The thicker root supports the rest of the tooth; the second molar is worn out and shed before the beginning of the second year.

The *third molar*, answering to *d* 4 in fig. 139, has the crown divided into from eleven to thirteen plates; it averages four inches in length and two inches in breadth, and has a small anterior, and a very large posterior root. It begins to appear above the gum about the end of the second year, is in its most complete state and extensive use during the fifth year, and is worn out and shed in the ninth year.

The *fourth molar*, answering to *m* 1 in fig. 139, presents a marked superiority of size over the third, and a somewhat different form. The anterior angle is more obliquely abraded, giving a pentagonal figure to the tooth in the upper jaw. The number of plates in the crown of this tooth is fifteen or sixteen; its length between seven and eight inches, its breadth three inches. It has an anterior simple and slender root supporting the three first plates; a second of larger size and bifid, supporting the four next plates; and a large contracting base for the remainder. The forepart of the grinding surface of this tooth begins to protrude through the gum at the sixth year; the tooth is worn away, and its last remnant shed, about the twentieth or twenty-fifth year. It is the homologue of the first true molar of ordinary Pachyderms.

The *fifth molar*, answering to *m* 2 in fig. 140, with a crown of from seventeen to twenty plates, measures between nine and ten inches in length, and about three inches and a half in breadth. The second root is more distinctly separated from the first simple root than from the large mass behind. It begins to appear above the gum about the twentieth year; its duration has not been ascertained by observation, but it probably is not shed before the sixtieth year.

The *sixth molar*, answering to *m* 3 in fig. 140, is the last, and has from twenty-two to twenty-seven plates; its length, or antero-posterior extent, following the curvature, is from twelve to fifteen inches; the breadth of the grinding surface rarely exceeds three inches and a half.

The reproductive power of the matrix in some cases surpasses that of the formative development of the cavity for lodging the tooth, and the last lamellæ are obliged to be folded from behind forwards upon the side of the tooth. Fig. 141 shows this condition in the last lower molar.

One may reasonably conjecture that the sixth molar of the Indian Elephant, if it make its appearance about the fiftieth year, would, from its superior depth and length, continue to do the work of mastication until the ponderous Pachyderm had passed the century of its existence.

The molars succeed each other from behind forwards, moving, not in a right line, but in the arc of a circle. The position of the growing tooth in the closed alveolus is almost at right angles with that in use. The grinding surface being at first directed backwards in the upper jaw, and forwards in the lower jaw; and being brought by the revolving course into a horizontal line in both jaws, so that the molars duly oppose each other when developed for use. The imaginary pivot on which the grinders revolve is next their root in the upper jaw, and is next the grinding surface in the lower jaw; in both towards the frontal surface of the skull. Viewing both upper and lower molars as one complete whole, subject to the same revolving movement, the section dividing such whole into upper and lower portions, runs parallel to the curve described by that movement, the upper being the central portion, or that nearest the pivot, the lower the peripheral portion. The grinding surface of the upper molars is consequently convex from behind forwards, and that of the lower molars concave. The upper molars are always broader than the lower ones. The bony plate forming the sockets of the growing teeth is more than usually distinct from the body of the maxillary, and participates in this revolving course, advancing forwards with the teeth. The partition between the tooth in use and its successor is perforated near the middle, and in its progress forwards that part next the grinding surface is first absorbed, the rest disappearing with the absorption of the roots of the preceding grinder.

Structure.

There are few examples of organs that manifest a more striking adaptation of a highly complex and beautiful structure to the exigencies of the animal endowed with it, than the grinding teeth of the Elephant. We perceive, for example, that the jaw is not encumbered with the whole weight of the massive tooth at once, but that it is formed by degrees as it is required; the division of the crown into a number of successive plates, and the subdivision of these into cylindrical processes, presenting the conditions most favourable to progressive formation. But a more important advantage is gained by this subdivision of the tooth; each part is formed like a perfect simple tooth, having a body of dentine, a coat of enamel, and an outer investment of cement. A single digital process may be compared to the simple canine of a Carnivore; a transverse row of these, therefore, when the work of mastication has commenced, presents,

Teeth of
Mammals.

by virtue of the different densities of their constituent substances, a series of cylindrical ridges of enamel, with as many depressions of dentine, and deeper external valleys of cement; the more advanced and more abraded part of the crown is traversed by the transverse ridges of the enamel inclosing the depressed surface of the dentine, and separated by the deeper channels of the cement; the forepart of the tooth exhibits its least efficient condition for mastication; the inequalities of the grinding surface being reduced in proportion as the enamel and cement which invested the dentinal plates have been worn away: this part of the tooth is, however, fitted for the first coarse crushing of the branches of a tree; the transverse enamel ridges of the succeeding part of the tooth divide it into smaller fragments, and the posterior islands and tubercles of enamel pound it to the pulp fit for deglutition. The structure and progressive development of the tooth not only give the Elephant's grinder the advantage of the uneven surface which adapts the millstone for its office, but, at the same time, secure the constant presence of the most efficient arrangement for the finer comminution of the food at the part of the mouth which is nearest the throat.

With regard to the *microscopic structure* of the peculiar modification of dentine called "ivory," this is characterised partly by the minute size of the tubes, which, at their origin from the pulp-cavity, do not exceed $\frac{1}{1000}$ th of an inch in diameter; in their close arrangement, at intervals scarcely exceeding the breadth of a single tube; and, above all, on their strong and almost angular gyrations, which are much greater than the secondary curvatures of the tubes of ordinary dentine.

The dentinal tubes of ivory, as they radiate from the pulp-cavity, incline obliquely towards the pointed end of the tusk, and describe two slight primary curves—the first convex towards that end, the second and shorter one concave. These curves, in narrow sections from near the open base of the tusk, are almost obscured by the strong angular parallel secondary gyrations. The tubes divide dichotomously, at acute angles, and gradually decrease in size as they approach the periphery of the tusk.

The characteristic appearance of decussating curved striæ, with oblique rhomboidal spaces, so conspicuous on transverse sections or fractures of ivory, is due to the refraction of light caused by the parallel secondary gyrations of the tubes above described. The strong contour lines observed in longitudinal sections of ivory, parallel with the cone of the pulp cavity, and which are smaller, circular, and concentric, when viewed in transverse slices of the tusk, are commonly caused by strata of minute opaque cellules, which are unusually numerous in the interspaces of the tubes throughout the substance of the ivory, and by their very great abundance and larger size in the peripheral layers of cement. The close-set lateral branches of the dentinal tubes unite with the tubuli of the cells. The decomposition of the fossil tusk into superimposed conical layers takes place along the strata of the opaque cellules, and directly across the course of the gyrating dentinal tubes. By the minuteness and close arrangement of the tubes, and especially by their strongly undulating secondary curves, a tougher and more elastic tissue is produced than results from their disposition in ordinary dentine; and the modification which distinguishes "ivory" is doubtless essential to the due degree of coherence of so large a mass as the elephant's tusk, projecting so far from the supporting socket, and to be frequently applied in dealing hard blows and thrusts. The central part of the tusk, especially near the base of such as have reached their full size, is occupied by a slender cylindrical tract of modified ivory, perforated by a few vascular canals, which is continued to the apex of the tusk. It is not uncommon to find processes of osteo-dentine or imperfect bone-like ivory, projecting in a stalactitic form¹ into the interior of the pulp-cavity.

The musket-balls and other foreign bodies which are occasionally found in ivory, are immediately surrounded by osteo-dentine, in greater or less quantity.² It has often been a matter of wonder how such bodies should become completely imbedded in the substance of the tusk, sometimes without any visible aperture, or how leaden bullets may have become lodged in the solid centre of a very large tusk without having been flattened. The explanation is as follows:—A musket-ball, aimed at the head of an elephant, may penetrate the thin bony socket and the thinner ivory parietes of the wide conical pulp-cavity occupying the inserted base of the tusk. The hole is soon healed and filled up, by ossification of the periosteum of the socket and of the pulp next the thin wall of ivory which has been perforated. The ball sinks below the level of this cicatrix, and the presence of the foreign body exciting inflammation of the pulp, an irregular course of calcification ensues, which results in the deposition around the ball of a certain thickness of osteo-dentine. The pulp, then resuming its healthy character and functions, coats the surface of the osteo-dentine, inclosing the ball, together with the rest of the conical cavity into which that mass projects, with layers of normal ivory. By the continued progress of growth the ball so inclosed is carried forwards to the middle of the solidified part of the tusk.

¹ Haller seems to have been the first to notice these irregular internal deposits in the pulp-cavity of the elephant's tusk. *Elementa Physiologie*, tom. viii. p. 519.

² Cuvier, *Annales du Muséum*, tom. viii. p. 115 (1806). Goodsir, *Edinb. Philos. Trans.*, 1841, p. 97.

Teeth of
Mammals.

Should the ball have penetrated the base of the tusk of a young elephant, it may be carried forwards by the uninterrupted growth and wear of the tusk, until that base has become the apex, and be finally exposed and discharged by the continual abrasion to which the apex of the tusk is subjected.

Yet none of these phenomena prove the absolute non-vascularity of the tusk, but only the low degree of its vascularity. Blood circulates, slowly no doubt, through the prolongations of the pulp in the minute vascular canals which are continued through the centre of the ivory to the very apex of the tooth. And it is from this source that the fine tubular structure of the ivory obtains the correspondingly minute villi carrying the plasmatic colourless fluid by which its low vitality is maintained.

The matrix of the tusk consists of a large conical pulp, which is renewed quicker than it is converted, and thus is not only preserved, but grows up to a certain period of the animal's life. It is lodged in the cavity at the base of the tusk; this base is surrounded by the remains of the capsule—a soft vascular membrane of moderate thickness—which is confluent with the border of the base of the pulp, where it receives its principal vessels. The writer had the tusk and pulp of the great elephant at the Zoological Gardens longitudinally divided, soon after the death of that animal in 1847. Although the pulp could be easily detached from the inner surface of the pulp-cavity, it was not without a certain resistance; and when the edges of the co-adapted pulp and tooth were examined by a strong lens, the filamentary processes from the outer surface of the pulp could be seen stretching, as they were withdrawn from the dentinal tubes before they broke. They are so minute that, to the naked eye, the detached surface of the pulp seems to be entire, and Cuvier was thus deceived in concluding that there was no organic connection between the pulp and the ivory.

Each molar of the Elephant is formed in the interior of a membranous sac—the capsule, the form of which partakes of that of the future tooth, being cubical in the first molar, oblong in the last, and rhomboidal in most of the intermediate teeth; but always decreasing in vertical extent towards its posterior end, and closed at all points, save where it is penetrated by vessels and nerves. It is lodged in an osseous cavity of the same form as itself, and usually in part suspended freely in the maxillary bone; the bony socket being destined to form part of the socket of the tooth, the exterior of the membranous capsule is simple and vascular; its internal surface gives attachment to numerous folds or processes, as in most other Ungulate animals. The dentinal pulp rises from the bottom of the capsule, or that part which lines the deepest part of the alveolus, in the form of transverse parallel plates, extending towards that part of the capsule ready to escape from the socket. These plates adhere only to the bottom of the capsule; their opposite extremity is free from all adhesion. This summit is thinner than the base; it might be termed the edge of the plate, but it is notched or divided into many digital processes. The tissue of these digitated plates is identical with that of the dentinal pulp of simple mammalian teeth; it becomes also highly vascular at the parts where the formation of the dentine is in active progress. Processes of the capsule descend from its summit into the interspaces of the dentinal pulp-plates, and consequently resemble them in form; but they adhere not only by their base to the surface of the capsule next the mouth, but also by their lateral margins to the sides of the capsule, and thus resemble partition-walls, confining each plate of the dentinal pulp to its proper chamber; the margin of the partition opposite its attached base is free in the interspaces of the orifices of the dentinal pulp-plates. The enamel organ, which Cuvier appears to have recognised under the name of the internal layer of the capsule, is distinguished by its light blue subtransparent colour and usual microscopic texture.

For the details of the action of those parts of the complex matrix in the formation of the several tissues of the grinding tooth of the Elephant, reference may be made to the *Ossements Fossiles*¹ of Cuvier and the writer's *Odontography*,² in which the theories of excretion and conversion may be contrasted.

SECTION IV.—Application of Odontology to Classification.

True teeth being restricted to the Vertebrate classes, their application to zoology is proportionally limited; but in them they form more or less important, if not essential, aids to the classification and grouping of species.

In this relation, however, as zoological characters, teeth possess different degrees of value in different classes, the lowest degree being in the class of Fishes, and the highest in that of Mammals.

Numerous rows of teeth, gradually succeeding and displacing each other, characterise the higher organized, or Plagiostomous Fishes,

and particular modifications of form and size of their teeth distinguish the primary subdivisions of the Plagiostomous order. A few other groups are well defined by dental characters, as the Pyenodonts, Gymnodonts, Goniodonts, and Chetodonts. The teeth afford good characters for the sub-division of the Sea Breams (*Sparidae*), and Cuvier³ has availed himself of dental characters to establish four tribes of that natural family. But in most of the natural orders, and in many of the subordinate groups, the dental system is subject to very great diversity in regard to the form, number, and position of the teeth; and in some natural groups of Fishes, there is also a want of constancy in the structure of the teeth. There are extremely few genera of Fishes that can be characterised by a definite numerical dental formula, like that which is applicable to most of the Mammalian genera. Indeed, in the first introduction of true teeth into the animal series, regarded in the ascending order, they manifest, like the mouths of the *Polypi*, the stomachs of the *Polygastria*, the gills of the *Nereids*, and the generative organs of the *Tenies*, the principle of vegetative or irrelative repetition; and in many fishes are too numerous to be counted. The limits within which the teeth are applicable as means of classification in Fishes, have been attempted to be defined in the writer's *Odontography*. Traced from species to species, they are of great importance in the determination of the fossils of this class.

With regard to microscopic structure, certain of the modifications of dental tissues, defined in the introductory section of the present Essay, are peculiar to, and characteristic of, the piscine class. Unvascular, or fine-tubed dentine, forms the crown of the teeth in a few Fishes, but is more common in those of the higher classes, in which, however, it is always associated with enamel or cement, or with both substances.

With regard to the class *Reptilia*, the teeth serve to characterize smaller and more definite groups, as, *e. g.*, the venomous and non-venomous Ophidians, the acrodont, pleurodont, and thecodont Saurians. Certain genera, and even species, may likewise be known by peculiar forms of teeth; but these are exceptions, and it is rarely that a definite dental formula can be assigned as a generic character of a reptile. There is no decided modification of dental structure peculiar to any of the class of reptiles; the poison-fang is rather a modification of form. The labyrinthic structure reaches its maximum of complexity in the great extinct Sauroid Batrachian of the Keuper sand-stone, but "it also exists at the base of the tooth in a few fishes,"⁴ and specific instances of it in that class (*Lepidosteus* and a few other Sauroids) have since received illustrations in the works of Professor Agassiz⁵ and Dr Wyman.⁶

The only constant and general character of the teeth of the cold-blooded classes of *Vertebrata* is derivable from the brief period of their existence in the individual, so that the few which develop roots have these always simple and undivided, usually hollow, and with the germ of a successor in or near them.

With the exception of the composite dental masses of the Chimæroids and the anomalous rostral teeth in *Pristis*, no existing species of fish or reptile could be said to have permanent teeth: no extinct species of either class has yet been found with teeth having divided roots implanted in sockets; and the sole evidence of perpetual growth by a persistent pulp, has but lately been given by the singular extinct Saurians of South Africa, with two long canine tusks in the upper jaw, which must have grown and been maintained throughout life, of due size and strength; like the tusks of the Boar and Walrus.⁷

In the mammalian class the value of the dental organs, as characters of classification, is much greater than in reptiles or fishes. Yet there is a difference in this respect in the different orders, and the dental system of the monophyodont *Cetacea* and *Bruta* has a much greater range of variation, and a less constant relation to the other characters on which the families and genera are founded, than in the diphyodont species. But, with respect to these also, the value of the teeth as zoological characters has been over-rated.⁸

It is true, indeed, that the most manifestly natural mammalian genera are those, the species of which are provided with absolutely similar molar teeth, and that those genera which include species with molars of different forms do not present the same character of unity. It does not follow, however, that by combining species of mammals with similar molars, a group will be formed perfectly analogous to those which may be considered as the most natural. Neither the molar teeth nor any other solitary character will serve to establish a natural classification.

The molar teeth will least mislead in this respect where their modification is most extreme, as when they are adapted to divide the flesh of animals, in which case they must of necessity be associated with the faculties and instruments for seizing and destroying prey.

Teeth of
Mammals.

Teeth of
Mammals.

But molar teeth may be similarly modified, and equally well adapted, for crushing vegetable substances, which substances may be sought for by one species on the dry land, by a second in marshes, and by a third in the sea, or on the banks of rivers. The grinding surface of the molar tooth, for example, may for this purpose be elevated into a pair of transverse ridges, and we find such molars in the Kangaroo, the Tapir, and the Manatee, as also in the extinct *Diprotodon*, *Nothotherium*, and *Dinotherium*. The small anterior molars of the *Mastodon giganteus* likewise present this form. It would be difficult to select, from the Mammalian class, the constituents of a more heterogeneous group than would be constituted by the character which M. F. Cuvier has assigned as the true guide to the formation of the most natural and uniform genera in Mammalogy.

Even in regard to teeth adapted to carnivorous habits, were these characters to form the sole guides in classification, species of placental Mammalia would be associated with those of the implantal subclass; and M. F. Cuvier, in illustrating his generalization, observes:—"Les sarigues, les péramèles, et les dasyures se sont réunis aux Insectivores, &c. &c., et je crois avoir été conduit à ces modifications par des motifs légitimes."

The molar teeth, which are best adapted for dealing with vegetable food, as in the Rodents and the hoofed Mammals, shew modifications of the enamel-markings of the grinding surface which are characteristic of families, of genera, and, in many instances, of species; and which are of the greatest utility to the Palæontologist from their conspicuous and well-marked features, and their constancy.

It is interesting also to observe, that in their more general appearance, the patterns of the upper molars are more symmetrical in the *Ungulata*, with hoofs in even numbers (compare figs. 115, 118, 120, 125), than in those with hoofs in odd numbers (compare figs. 117, 130, 132).

SECT. IV.—HOMOLOGIES OF THE TEETH.

Homologies of the
Teeth.

The idea of a recognition of answerable teeth in different animals has prevailed, more or less vaguely, in Anatomy, from an early period of the science.

When "incisors," "canines," and "molars" were predicated of the dentition in different species, homologous teeth were recognised so far as the characters of those classes of teeth were defined and understood.

The Cuviers² went a step further, and distinguished the molar teeth into "false" and "true," into "carnassial" and "tubercular." De Blainville pointed out a particular tooth by the name of "principal," which he believed himself able to trace from species to species.³

The results of the writer's researches into the homologies of the teeth are given in his *Odontography* in the *Transactions of the British Association* for 1839, and in those of the *Royal Society* for 1850, p. 481.

The first step in this inquiry is the elimination of those classes of *Vertebrata* and orders of *Mammalia* in which homology cannot be predicated of individual teeth. This limits the work to the group of Mammals which the writer has termed "Diphyodonts."

Only in the Mammalian orders with two sets of teeth do those organs acquire fixed individual characters, supporting the application of special denominations; and this individualization of the teeth is eminently significative of the high grade of organization of the animals manifesting it.

Originally, indeed, the name "incisors," "lanaries" or "canines," "molars," "false molars," were given to the teeth in Man and certain Mammals, as in Reptiles, in reference merely to the shape and offices so indicated; but names of teeth can now be used as arbitrary signs, in a more fixed and determinate sense. In some *Carnivora*, e.g., the front teeth have broad tuberculate summits, adapted for nipping and bruising, while the principal back-teeth are shaped for cutting, and work upon each other like the blades of scissors. The front teeth in the

Elephant project from the upper jaw in the form, size, and direction of long pointed horns. In short, shape and size are the least constant of dental characters; and the homologous teeth are determined, like other parts, by their relative position, by their connections, and by their development.

Homologies of the
Teeth.

Those teeth which are implanted in the premaxillary bones, and in the corresponding part of the lower jaw, are called "incisors," whatever be their shape or size. The tooth in the maxillary bone, which is situated at, or near to, the suture with the premaxillary, is the "canine," as is also that tooth in the lower jaw which, in opposing it, passes in front of its crown when the mouth is closed. The other teeth of the first set are the "deciduous molars;" the teeth which displace and succeed them vertically are the "premolars;" the more posterior teeth, which are not displaced by vertical successors, are the "molars," properly so called.

The premolars must displace deciduous molars in order to rise into place; the molars have no such relations. It will be observed in fig. 17 that the last deciduous molar (*d* 4) has the same relative superiority of size to *d* 3 and *d* 2 which *m* 3 bears to *m* 2 and *m* 1; and the crowns of *p* 3 and *p* 4 are of a more simple form than those of the milk-teeth which they are destined to succeed. This, however, is not a constant or essential character. Teeth of each of the kinds arbitrarily termed "incisors," "canines," "false molars," and "molars," have received other special names, having reference to certain peculiarities of form or other property. The "false molars" in the human subject have been called "bicuspid." The last upper premolar and the first true molar in the *Carnivora* are termed "sectorials," or "molaires carnassières." Teeth of an elongated conical form, projecting considerably beyond the rest, and of uninterrupted growth, are called "tusks;" such, for example, are the incisors of the Elephant, Narwhal, *Dinotherium*, and Dugong, the canines of the Boar, Walrus, and Hippopotamus. The long and large incisors of the Rodents have been termed, from the shape and structure of their cutting edge, scalpriform teeth, chisel teeth, "*dentes scalprarii*." The lower incisors of the Flying Lemurs (*Galeopithecus*), with the crown deeply notched like a comb, are termed "*dentes pectinati*." The canines of the Baboons, which are deeply grooved in front like the poison-fangs of some snakes, are "*dentes canaliculati*." The compressed crowns of the teeth of short-clawed Seals (*Stenorhynchus*) and of the extinct *Zeuglodon*, being divided into points like a saw, are "*dentes serrati*," etc. But a true knowledge of nature, a right appreciation of what is essential in her phenomena, tends to explode needless terms of art invented for unimportant varieties, and to establish those terms that are the signs of true species of things.

As most zoologists have adopted the Cuvierian system of nomenclature and homology of the teeth in Mammalia, it may not be superfluous to explain what is here deemed objectionable in that system. In it the molar series of teeth, or those that follow the canines, are divided, according to their form, into three kinds, "false molars," "carnassials," and "tubercular molars," and the generic dental characters of the Mammalia are formulized according to this system. Thus, the genus *Felis* has—"fausses molaires" $\frac{2.3}{2.2}$, "carnassières" $\frac{1.1}{1.1}$, "tuberculeuses" $\frac{1.1}{0.0} = \frac{8}{8}$. This seems a true and natural way of expressing the homotypal teeth, or the answerable teeth in the upper and lower jaw. But to illustrate its error, the subjoined diagram (fig. 145) is appended, in which the dental

Homologies of the Teeth. system of the Cat-tribe (*Felis* V.) is associated with that of other Mammals, and in which the line marked "Cuvier" intersects the teeth in each jaw, called "carnassières," those anterior to them being the teeth called

teeth in advance of the carnassial in the upper jaw (*p* 3, Homologies of the Teeth. *p* 2) in like manner are opposed to the same number of "fausses molaires" in the under jaw, and the canine (*c*) above plays upon the canine below; all seems fitting and symmetrical, save that the little tubercular (*m* 1) above has no opponent in the lower jaw. And, perhaps, the close observer might notice that, whilst the upper canine (*c*) glides behind its homotype below, the first upper false molar (*p* 2) passes anterior to the crown of the first false molar (*p* 3) below; and that the second false molar and carnassial of the upper jaw are also a little in advance of those teeth in the under jaw when the mouth is shut.

In passing to the dentition of the Dog (fig. III. *Canis*), formulated by Cuvier as "fausses molaires $\frac{3.3}{4.4}$, carnassières $\frac{1.1}{1.1}$, tuberculeuses $\frac{2.2}{2.2} = \frac{12}{14}$,"¹ it will be observed that here the first upper false molar (*p* 1) differs from the first (*p* 2) in *Felis*, inasmuch as, when the mouth is shut, it preserves the same relative position to its opponent below (*p* 1, in fig. III.) which the upper canine does to the lower canine, and that the same may be said of the second and the third false molars; but that, with regard to the carnassial above (*p* 4), this tooth repeats the same relative position in regard to the fourth false molar below (*p* 4), and not to that tooth (*m* 1) which Cuvier regarded as the lower homotype of the carnassial; and, indeed, the more backward position of the lower carnassial is so slight that its significance might well be overlooked, more especially as the two succeeding tubercular teeth above were opposed to two similar tuberculars below.

How unimportant size and shape are, and how significant relative position is, in the determination of the homologies of teeth as of other parts, may be learnt before quitting the natural order of Carnivora; *e. g.* by the condition of the dental system in the Bear (fig. II. *Ursus*). Here the lower tooth (*m* 1), instead of presenting the carnassial character, and resembling in form the upper tooth (*p* 4), which is the homologue of the upper carnassial in the dog, has a tubercular crown, and corresponds in size as well as shape with the upper tooth (*m* 1), to which it is almost wholly opposed, and with the same slight advance of position which we observe in the lower canine as compared with the upper one, and in the four lower premolars (*p* 1, *p* 2, *p* 3, *p* 4) as compared with their veritable homotypes above. F. Cuvier divides the molar series of the genus *Ursus* into "fausses molaires $\frac{3.3}{4.4}$, carnassières $\frac{1.1}{1.1}$, tuberculeuses $\frac{2.2}{2.2} = \frac{12}{14}$,"² The tendency in every thinker to generalise and to recognise Nature's harmonies, has led him here to use the term "carnassière" in an arbitrary sense, and to apply it to a tooth above (II. *p* 4), which he owns has such a shape and diminished size as would have led him to regard it as merely a false molar, but that the upper carnassial would then have entirely disappeared; and it has also led him to give the name "carnassière" to a tooth below (*m* 1), which he, nevertheless, describes as having a tubercular and not a trenchant crown. In so natural a group as the true Carnivora, it was impossible to overlook the homologues of the trenchant carnassials of the lion, even when they had become tubercular in the omnivorous bear; and Cuvier, therefore, having determined and defined the teeth so called in the feline genus, felt compelled to distinguish them by the same names after they had lost their formal specific character. And if, indeed, he had succeeded in discovering the teeth which were truly answerable or homotypal in the upper and lower jaws, the term "carnassial" might have been retained as an arbitrary one for such teeth, and have been applied to their homologues in

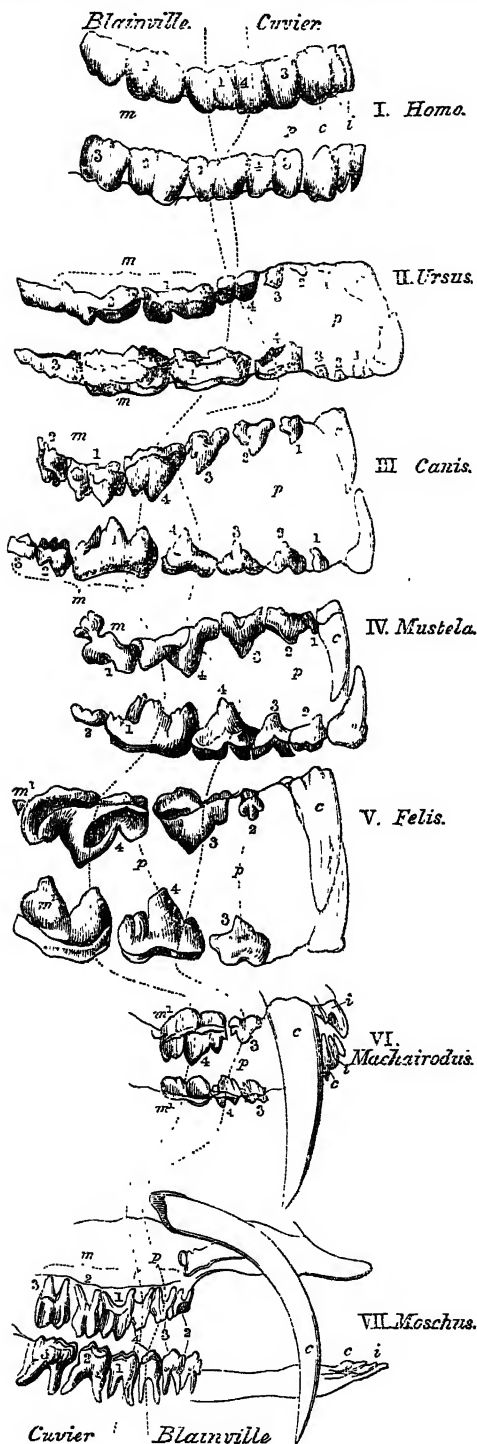

Fig. 145.
Homologies of Teeth.

"fausses molaires;" those behind—a single tooth in the upper jaw of *Felis*—being the "tuberculeuses." In this genus the tooth (*p* 4) above chiefly plays upon the tooth (*m* 1) below, which has a similar sectorial or carnassial modification of form; they fit, indeed, almost as Cuvier describes, like the blades of a pair of scissors. The two

² Op. cit. p. 109.

Homologies of the Teeth.

Man, the Ruminant, or the Pachyderm, where they are as certainly determinable as in those aberrant Carnivores, in which they have equally lost their sectorial shape.

But the inconvenience of names indicative of such specialties of form will be very obvious when the term "tuberculeuses" comes to be applied to the three hindmost teeth in the *Hyænodon* (fig. 113), which teeth answer to the broad crushing teeth, *m* 1, *m* 2, and *m* 3, in the bear and some other existing *Carnivora*. The analogous term "molar" having a less direct or descriptive meaning, is therefore so much the better, as the requisite arbitrary name of a determinate species of teeth.

Had Cuvier been guided in his determinations of the teeth by their mutual opposition in the closed mouth, and had studied them with this view in the *Carnivora*, with the dentition most nearly approaching to the typical formula, viz. the bear, he could then have seen that the three small and inconstant lower premolars (*p* 1, *p* 2, *p* 3) were the homotypes of the three small and similarly inconstant premolars above; that the fourth false molar (*p* 4 below), which, as he observes, "alone has the normal form,"¹ was truly the homotype of the tooth above (*p* 4), which he found himself compelled to reject from the class of "fausses molaires," notwithstanding it presented their normal form; that the tubercular tooth (*m* 1) which he calls "carnassière" in the lower jaw, was the veritable homotype of his first "molaire tuberculeuse" above (*m* 1), and that the tooth in the inferior series, which had no answerable one above, was his second "tuberculeuse" (*m* 3) in the present Essay. The true second tubercular above (*m* 2) is, however, so much developed in the bear as to oppose both *m* 2 and *m* 3 in the lower jaw, and it might seem to include the homotypes of both those teeth coalesced. One sees with an interest such as only these homological researches could excite, that they were distinctly developed in the ancient *Amphicyon* (fig. 114), which accordingly presents the typical formula.

Thus the study of the relative position of the teeth of the bear might have led to the recognition of their real nature and homologies, and have helped to raise the mask of the extreme formal modifications, by which they are adapted to the habits of the more blood-thirsty *Carnivora*. But the truth is plainly and satisfactorily revealed when we come to trace the course of development and succession of these teeth. The weight which must ever attach itself to an opinion sanctioned by the authority of both the Cuviers, demands that a conclusion contrary to theirs, and which seems to be opposed by Nature herself in certain instances, should be supported by all the evidence of which such conclusion is susceptible.

It is proposed, therefore, first, to show how, in the bear, the writer's determinations of the teeth are established by their development, as well as by their relative position. As the question only concerns the molar series, the remarks will be confined to those teeth. In the jaws of the young bear, figured in cut 110, the first premolar is the only one of the permanent series in place; the other grinders in use are the deciduous molars, *d* 2, *d* 3, and *d* 4; *d* 2 will be displaced by *p* 2, *d* 3 by *p* 3, and *d* 4, by the tooth *p* 4, which, notwithstanding its size and shape, Cuvier felt himself compelled to discard from the series of false molars, but which we now see is proved by its developmental relations to *d* 4, as well as by its relative position and similarity to *p* 4 in the lower jaw (fig. 145,

Ursus) to be veritably the last of the premolar series, and to agree not in shape only, but in every essential character, with the three preceding teeth called by Cuvier "fausses molaires." So, likewise, in the lower jaw, it is seen that the primitive deciduous series (*d* 1, *d* 2, *d* 3, and *d* 4) will be displaced by the corresponding premolars (*p* 1, *p* 2, *p* 3, and *p* 4); and that the tooth *m* 1, called carnassière by Cuvier, in the lower jaw, differs essentially from that (*p* 4) so called in the upper jaw, by being developed without any vertical predecessor or deciduous tooth.

Homologies of the Teeth.

The same law of development and succession prevails in the genus *Canis*, as may be readily seen in the jaws of a dog of ten months' age. Although the tooth (*m* 1, III. fig. 145) in the lower jaw has exchanged the tubercular for the carnassial form, it is still developed, as in the bear, behind the deciduous series, and independently of any vertical predecessor; and the tooth (*p* 4) above, although acquiring a relative superiority of size to its homologue in the bear, and more decidedly a carnassial form, is not the homotype of the permanent carnassial below, but of that premolar (*p* 4) which displaces the deciduous carnassial (*d* 4). The symbols in fig. 145 III. sufficiently indicate the relations of the other teeth, and the conclusions that are to be drawn from them as to their homologies.

In the genus *Felis* (fig. 104), the small permanent tubercular molar of the upper jaw (*m* 1) has cut the gum before its analogue (*d* 4) of the deciduous series has been shed; but though analogous in function, this tooth is not homologous with, or the precedent tooth to *m* 1, but precedes the great carnassially modified premolar (*p* 4). In the lower jaw the tooth (*m* 1) which is functionally analogous to the carnassial above, is also, as in the dog, the first of the true molar series, and the homotype of the little tubercular tooth (*m* 1) above. And the homologies of the permanent teeth (*p* 4 and *m* 1 below, fig. 145, V.), with those so symbolised in the dog (fig. 145, III.), teach us that the teeth which are wanting in the feline, in order to equal the number of those in the canine dentition, are *m* 2 in the upper jaw, *m* 2 and *m* 3 in the lower jaw; *p* 1 in the upper jaw, *p* 1 and *p* 2 in the lower jaw; thus illustrating the rule, that, when the molar series falls short of the typical number, it is from the two extremes of such series that the teeth are taken, and that so much of the series as is retained is thus preserved unbroken. In the great extinct sabre-toothed tiger (*Machairodus*, fig. 145, VI.), the series is still further reduced by the loss of *p* 2 in the upper jaw.

That the student may test for himself the demonstration which the developmental characters above defined yield of the true nature and homologies of the feline dentition, the most modified of all in the terrestrial *Carnivora*, he is recommended to compare with Nature the following details of the appearance and formation of the teeth in the common cat. In this species the deciduous incisors (*d* 1) begin to appear between two and three weeks old; the canines (*d* 2) next, and then the molars (*d* 3) follow, the whole being in place before the sixth week. After the seventh month they begin to fall in the same order; but the lower sectorial molar (*m* 1) and its tubercular homotype above (*m* 1) appear before *d* 2, *d* 3, and *d* 4 fall. The longitudinal grooves are very faintly marked in the deciduous canines. The first deciduous molar (*m* 2) in the upper jaw is a very small and simple one-fanged tooth; it is succeeded by the corresponding

¹ *Dents des Mammifères*, p. 111.

² *Machairodus*, from *μάχαιρα*, a sabre; and *ὀδὸν*, a tooth. This generic name was imposed by Dr Kaup on the extinct animal which was armed with canine teeth, like that in the above figure (c). Such teeth, long, compressed, falciform, sharp-pointed, and with anterior and posterior finely-serrated edges, were first discovered in tertiary strata in Italy and Germany, and were referred by Cuvier to a species of bear, under the name of *Ursus cultridens*.

Homologies of the Teeth.

tooth of the permanent series, which answers to the second premolar ($p\ 2$) of the hyæna and dog. The second deciduous molar ($m\ 3$) is the sectorial tooth; its blade is trilobate, but both the anterior and posterior smaller lobes are notched, and the internal tubercle, which is relatively larger than in the permanent sectorial, is continued from the base of the middle lobe, as in the deciduous sectorial of the dog and hyæna; it thus typifies the form of the upper sectorial, which is retained in the permanent dentition of several Viverrine and Musteline species. The third or internal fang of the deciduous sectorial is continued from the inner tubercle, and is opposite the interspace of the two outer fangs. The Musteline type is further adhered to by the young Feline in the large proportional size of its deciduous tubercular tooth ($d\ 4$). In the lower jaw, the first milk-molar ($d\ 3$) is succeeded by a tooth ($p\ 3$) which answers to the third lower premolar in the dog and civet. The deciduous sectorial ($d\ 4$), which is succeeded by the premolar ($p\ 4$), answering to the fourth in the dog, has a smaller proportional anterior lobe, and a larger posterior talon, which is usually notched; thereby approaching the form of the permanent lower sectorial tooth in the *Mustelidæ*.

When the premolars and the molars are below their typical number, the absent teeth are missing from the fore-part of the premolar series and from the back-part of the molar series. The most constant teeth are the fourth premolar and the first true molar; and these being known by their order and mode of development, the homologies of the remaining molars and premolars are determined by counting the molars from before backwards, *e. g.*, "one," "two," "three;" and the premolars from behind forwards, "four," "three," "two," "one."

Examples of the typical diphyodont dentition are exceptions in the actual creation; but it was the rule in the earlier forms of placental Mammalia, whether the teeth were modified for animal or vegetable food.

Not only the *Hyænodon* (fig. 113) and *Amphicyon* (fig. 114), but the *Dichodon* (fig. 118), *Anoplotherium*, *Palæotherium*, *Chæropotamus*,¹ *Anthracotherium*,² *Hypopotamus*,³ *Hyracotherium*,⁴ and other ancient (eocene and miocene) tertiary Mammalian genera presented the forty-four teeth, in number and kind according to that which is here propounded as the typical or normal dentition of the placental Mammalia.⁵ When the clue is afforded, by the observed development and succession of the teeth, to their homologies, it infallibly conducts us to the true knowledge of the nature both of the teeth which are retained, and of those which are wanting to complete the typical number. We have availed ourselves of this in deciphering the much modified dentition of the genus *Felis*; and the same clue will guide us to the knowledge of the precise homologies of the teeth in our own species.

The discovery by the great poet Goëthe of the limits of the premaxillary bone in Man leads to the determination of the incisors, which are reduced to two on each side of both jaws; the contiguous tooth shows by its shape as well as position that it is the canine, and the characters of size and shape have also served to divide the remaining five teeth in each lateral series into two bicuspid and

Homologies of the Teeth.

three molars. In this instance the secondary characters conform with the essential ones. But since we have seen of how little value shape or size are, in the order *Carnivora*, in the determination of the exact homologies of the teeth, it is satisfactory to know that the more constant and important character of development gives the requisite certitude as to the nature of the so-called bicuspid in the human subject. In fig. 100, the condition of the teeth is shown in the jaws of a child of about six years of age. The two incisors on each side ($d\ i$) are followed by a canine (c), and this by three teeth having crowns resembling those of the three molar teeth of the adult. In fact, the last of the three is the first of the permanent molars; it has pushed through the gum, like the two molars which are in advance of it, without displacing any previous tooth, and the substance of the jaw contains no germ of any tooth destined to displace it; it is therefore, by this character of its development, a true molar, and the germs of the permanent teeth, which are exposed in the substance of the jaw between the diverging fangs of the molars ($d\ 3$ and $d\ 4$), prove them to be temporary, destined to be replaced, and prove also that the teeth about to displace them are premolars. According, therefore, to the rule previously laid down, we count the permanent molar in place the first of its series ($m\ 1$), and the adjoining premolar as the last of its series, and consequently the fourth of the typical dentition ($p\ 4$).

We are thus enabled, with the same scientific certainty as that whereby we recognise in the middle toe of our foot the homologue of that great digit which forms the whole foot, and is encased by the hoof, in the horse, to point to $p\ 4$, or the second bicuspid in the upper jaw, and to $m\ 1$, or the first molar in the lower jaw, of man (fig. 145, I.), as the homologues of the great carnassial teeth of the lion ($p\ 4$, $m\ 1$, fig. 145, V.) We also conclude that the teeth which are wanting in man to complete the typical molar series, are the first and second premolars, the homologues of those marked $p\ 1$ and $p\ 2$ in the bear (fig. 145, II.) The characteristic shortening of the maxillary bones required this diminution of the number of their teeth, as well as of their size, and of the canines more especially; and the still greater curtailment of the premaxillary bone is attended with a diminished number and an altered position of the incisors. One sees, indeed, in the carnivorous series, that a corresponding decrease in the number of the premolars is concomitant with the shortening of the jaws. Already in the *Mustelidæ* (fig. 145, IV.), the first premolar below is abrogated; in *Felis* also above, with the further loss of the second premolar in the lower jaw; the true molars being correspondingly reduced in these strictly flesh-eating animals, but taken away from the back part of their series.

The homologous teeth being thus determinable, they may be severally signified by a symbol as well as by a name. The incisors, *e. g.*, are represented in the present Essay (See figs. 20 and 118) by their initial letter i ; and individually by an added number, $i\ 1$, $i\ 2$; and $i\ 3$; the canines by the letter c ; the premolars by the letter p ; and the molars by the letter m ; these also being differentiated by added numerals. Thus, the number of these

¹ *History of British Fossil Mammalia*, p. 416, fig. 164.

² *Quarterly Journal of the Geological Society*, May 1848, p. 103, pl. viii.

³ Thirty-eight instances are cited in the writer's memoir on "Pholophus," *Quarterly Journal of the Geological Society*, May 1857. The seeming exception afforded by the oolitic *Plagiaulax*, on which much stress is laid by Lyell (Supplement to *Manual of Geology*, p. 21), bears upon the generalisation with about the same value as the abnormal dentition of *Proteles* does upon the generalised dental formula of the genus *Canis*. It is objected that "we ought, in every great family of the Mammalia, to find evidence of closer adherence to the archetype the farther we recede in time" (*ib.*, p. 22). And the *Plagiaulax* is cited as evidence to the contrary. But the force of the argument really lies in the suppression of the fact, that all the other known instances of the same great Marsupial family, from oolitic strata, do give evidence of such closer adherence to archetype. The type of the Diphyodont dentition is a modification of the wider Vertebrate type of dentition; and the great majority of known oolitic Mammals exhibit that greater degree of vegetative repetition of teeth (as in fig. 74), which the theory, rightly understood, would have anticipated.

Homologies of the Teeth. teeth, on each side of both jaws, in any given species, Man, *e. g.*, may be expressed by the following brief formula:—

$$i \frac{2.2}{2.2}; c \frac{1.1}{1.1}; p \frac{2.2}{2.2}; m \frac{3.3}{3.3} = 32;$$

and the homologies of the individual teeth, in relation to the typical formula, may be signified by *i* 1, *i* 2; *c*; *p* 3, *p* 4; *m* 1, *m* 2, *m* 3; the suppressed teeth being *i* 3, *p* 1, and *p* 2.

If we were desirous of further testing the soundness of the foregoing conclusions as to the nature of the teeth absent in the reduced dental formula of man, we ought to trace the mode in which the type is progressively resumed in descending from man through the order most nearly allied to our own.

Through a considerable part of the Quadrumanous series, *e. g.*, in all the Old World genera above the Lemurs, the same number and kinds of teeth are present as in man, the first deviation being the disproportionate size of the canines and the concomitant break or "diastema" in the dental series for the reception of their crowns when the mouth is shut. This is manifested in both the Chimpanzees and Orangs, together with the sexual difference in the proportions of the canine teeth. Then comes the added premolar in the New World Monkeys, and the further additions in lower quadrupeds, until in the Hog genus we see the old primitive type of Diphyodont dentition resumed or retained.

The typical dentition is departed from in the existing Hippopotamus by the early loss of *p* 1, and the reduction of the incisors to $\frac{2}{3}$ in both jaws; in the extinct Hippopotamus of India, *p* 1 was longer retained, and the incisors were in normal number $\frac{2}{3}$; whence the term *Hexaprotodon* proposed for this interesting restoration by its discoverers, Cautley and Falconer.

The existing even-toed or artiodactyle *Ungulata* superadd the characters of simplified form and diminished size to the more important and constant one of vertical succession in their premolars.¹ These teeth in the Ruminants, *e. g.* (fig. 145, VII., *Moschus*, *p* 2, 3, 4.), represent only the moiety of the true molars, or one of the two semi-cylindrical lobes of which those teeth consist, with, at most, a rudiment of the second lobe, as Cuvier very accurately describes, and F. Cuvier figures in pl. 94 of his useful work, *Dents des Mammifères*. An analogous morphological character of the premolars will be found to distinguish them in the dentition of the genus *Sus* (fig. 20), in the Hippopotamus, and in the *Phacocharus* (fig. 124), where the premolar series is greatly reduced in number: yet this instance of a natural affinity manifested in so many other parts of the organization of the artiodactyle genera has been overlooked in F. Cuvier's work above cited, although it is expressly designed to show how such zoological relations are illustrated by the teeth. Confiding in the accuracy of the Baron Cuvier's division of the hoofed quadrupeds into "Pachyderms" and "Ruminants," M. F. Cuvier separates the non-ruminant artiodactyles from the ruminant genera of the same natural division, by interposing the Tapir, Hyrax, Rhinoceros, and Elephant; whilst the Horse, which, in the size and complexity of its premolars, as well as in many other characters, agrees closely with the other perissodactyle Ungulates, is placed in close juxtaposition with the Ruminants.

Most of the deciduous teeth of the Ruminants resemble in form the true molars; the last, *e. g.* (fig. 121, *d* 4), has three lobes in the lower jaw, like the last true molar (*m* 3).

Sufficient, it is hoped, has been adduced to prove that the molar series of the Diphyodonts is naturally divisible into only two groups, premolars and molars; that the typical number of these is $\frac{2}{3}$, $\frac{2}{3}$; and that each individual tooth may be determined and symbolised throughout the series, as is shown in the instances under cut 145. If anything were wanting to prove the artificial character of a threefold division of these teeth, and the futility of any other classification than that founded upon development, it would be afforded by the attempt to determine the homologous teeth, which is exemplified by the dotted line which traverses the series, and which crosses the teeth distinguished by the name "principales" in the great "*Ostéographie and Odontographie*" of De Blainville.

This author abandons the classification of the molar series adopted by the Cuviers, without assigning his objections to it, and proposes another, in which he divides the series into "avant-molaires, principales, and arrière-molaires;" he exemplifies this division by the human dentition, in which the five grinders on each side of both jaws are formulised as "two avant-molaires, one principale, and two arrière-molaires."²

With regard to the characters of these kinds of teeth, the avant-molaires are "simple or complex," the principale is "trenchant," and the arrière-molaires are "tuberculous." But as shape is not a constant character, especially in the "principale," the author proposes another from its position, describing it as "being implanted below the root of the zygomatic process of the maxillary bone" in the upper jaw; and stating that the tooth which opposes it below, and is in advance of it, is the lower "principale."

In defining the dentition of the genus *Felis*, M. de Blainville accordingly assigns one "avant-molaire," one "principale," and two "arrière-molaires" in the upper jaw; and one "avant-molaire," one "principale," and one "arrière-molaire" in the lower jaw.³ In another part of the same work, he, however, proposes another formula, viz., two "avant-molaires," one "principale," and one "arrière-molaire" above; one "avant-molaire," one "principale," and one "arrière-molaire" below; but, taking either of these determinations, or the dental formulæ which he assigns to other carnivorous genera, and comparing them with his formula of the molar series in the Quadrumana and Man, we find that a tooth which displaces and succeeds a milk-tooth in one species is made the homologue of a tooth, which, in Man and Quadrumana, rises above the gum without displacing any predecessor; in other words, the "principale" is a premolar in certain genera, and a true molar in other genera. Reference may be made to the concluding pages of the chapter on the teeth of the Carnivora in the writer's *Odontography*, p. 514, for further proofs that a "molaire principale" does not exist in nature; that the characters by which it is defined by M. de Blainville are artificial; and that they fail in their application to determine the teeth in the series of placental Mammalia with deciduous and permanent teeth.

In the series of figures under cut 145, the line, "Cuvier," traverses the tooth or its homologue, from Man to the Ruminant, which Cuvier distinguished as the "molaire carnassière;" the other line traverses that tooth which M. de Blainville distinguishes as the "molaire principale;" the letters and numbers symbolise the teeth, and indicate their individual homologies, and the binary division of the molar series, which it has been one object of the present Essay to illustrate. To show how these symbols may be applied to the exposition of facts in the

¹ See the writer's "Remarks on the Classification of the Hoofed Quadrupeds," in *Quarterly Journal of the Geological Society*, May 1848. The older Eocene genera, *e. g.*, *Lophiodon* and *Pholophus*, manifest a minor departure from type in a less changed form of one or two of the hinder premolars.

³ *Ostéographie*, p. 43.

Homologies of the Teeth.

comparative anatomy of the teeth, the difficult homology of the proboscidean dentition, and the complex and intricate subject of the succession of the teeth in the kangaroo, will be finally selected.

With regard to the homologies of the complex molars of the proboscidean quadrupeds, a species of insight which may come to be deemed, in the course of anatomical science, as of equal import to the knowledge of the formative process of parts, it may be admitted that the mere fact of the marked and disproportionate increase of size of the first of the three last molars (fig. 139, *m* 1) over its predecessor (*d* 4), the last of the first three that are developed, seems to be but a feeble support to the analogical evidence on which chiefly the three last molars of the elephant are here classed in a category distinct from that of their smaller predecessors. But the value of such indication and analogy will begin to be apparent when we examine the condition of dental development in the primeval forms of Proboscideans. It has already been shewn that the typical character of the Diphyodont dentition was more closely and generally adhered to in the genera that existed in the old tertiary periods in geology than in their actual successors; it became, of course, highly interesting to inquire whether the Miocene *Mastodons*, the earliest of the great proboscidean quadrupeds of which we have any cognizance, manifested any analogous closer adhesion to type than their elephantine successors, and whether they would afford any actual proof of the true deciduous nature of the first, second, or third molars, by the development of a vertical successor or premolar. Cuvier first ascertained the fact, though without appreciating its full significance, in a specimen of the upper jaw of the *Mastodon angustidens* from Dax, in which the second six-lobed deciduous molar was displaced by a four-lobed or quadricuspid premolar developed above it, and succeeding it vertically. The same important fact was subsequently confirmed by Dr Kaup, in observations of the *Mastodon angustidens* (his *Mast. longirostris*) of the *Miocene* of Eppelsheim.

This satisfactorily proves the true deciduous character of the first and second molars (fig. 139, *d* 2 and 3); and, that the third molar in the order of appearance (*d* 4) is also one (the last) of the deciduous series, is indicated, both by the contrasted superiority of size of the tooth (*m* 1), and the more direct evidence which a comparison with the dentition of the wart-hog (fig. 124) affords, that *m* 1, fig. 139, is the first of the true molars. The great extent and activity of the processes of dental development required for the preparation of the large and complex true molar teeth, would seem to exhaust the power in Proboscideans, which, in ordinary Pachyderms, is expended in developing the vertical successors of the deciduous teeth. In the miocene *Mastodon* above cited, this normal exercise of the reproductive force was not, however, wholly exhausted; and one premolar (fig. 139, *p* 3), of more simple form than its deciduous predecessor, was developed on each side of both jaws; but even this trace of adherence to the archetypal dentition is lost in the more modified Proboscideans of the present day. Another and interesting mark of adhesion to the archetype was shown by the development of two incisors in the lower jaw in the young of some of the *Mastodons*, by the retention and development of one of these inferior tusks in the male of the *Mastodon giganteus* of North America, and by the retention of both in the European *Mastodon angustidens* (fig. 140). No trace of these inferior homotypes of the premaxillary tusks have been detected in the foetus or young of the existing elephants. In the gigantic *Dinotherium*, the upper incisors were suppressed, and the lower incisors were developed into huge tusks, which curved down from the symphysis of the massive lower jaw.

Homologies of the Teeth.

The chief modifications of the marsupial dentition have already been described and illustrated. The observed phenomena of the development and change of the teeth led to the generalisation that the marsupial differed from the placental Diphyodont mammals in having four true molars, *i. e.*, *m*. $\frac{4.4}{4.4}$ instead of *m*. $\frac{3.3}{3.3}$; and also that they differed in having only three premolars, *i. e.* *p*. $\frac{3.3}{3.3}$ instead of *p*. $\frac{4.4}{4.4}$; the typical number of the grinding series, $\frac{7.7}{7.7}$, being the same. Since, however, there is reason to conclude that *m* 1 in the placental series, as, *e. g.*, figs. 17 and 124, is a continuation of the deciduous series of molars, which might be symbolised as *d* 5, and only becomes a permanent molar because there is no premolar developed above it, so we may regard the tooth marked *m* 1 in figs. 75, 76 and 78 as being an antecedent tooth of the deciduous series, rendered permanent by a like reason, the suppression, *viz.* of *p* 4. In other words, that *m* 1 in fig. 75 is the homologue of *d* 4 in fig. 17, and that the true homologue of *p* 4 is not developed in the *Marsupialia*.

The homologues of the teeth of the Kangaroo are illustrated in fig. 146, according to this idea of them.

The permanent dental formula of both the *Macropodidae* and *Hypsiprymnidae*, according to the usual view, as given at p. 449, is—

$$i \frac{3.3}{1.1}; c \frac{1.1}{0.0}; p \frac{1.1}{1.1}; m \frac{4.4}{4.4} = 30.$$

According to the real state of things it is—

$$i \frac{3.3}{1.1}; c \frac{1.1}{0.0}; p \frac{1.1}{1.1}; d \frac{1.1}{1.1}; m \frac{3.3}{2.2} = 30.$$

The canines, which are confined to the upper jaw, are small or minute when retained; and disappear after being represented "en germe" in most of the true Kangaroos.

The deciduous dentition of the great Kangaroo (*Macropus major*) is—

$$i \frac{3.3}{1.1}; c \frac{1.1}{0.0}; m \frac{2.2}{2.2} = 18.$$

The canines are rudimental, and are absorbed rather than shed. The deciduous incisors are shed before the young animal finally quits the pouch; when this takes place, the dentition is—

$$i \frac{1.1}{1.1}; d m \frac{2.2}{2.2} = 12;$$

the upper incisors being *i* 1, the molars *d* 2 and *d* 3 of the typical dentition. This stage is exemplified in the lower jaw at A (fig. 146). The next stage shows the acquisition of *i* 2 in the upper jaw, and *d* 4 in both jaws, and the formula is—

$$i \frac{2.2}{1.1}; d m \frac{3.3}{3.3} = 18 \text{ (B, fig. 146).}$$

At one year old, the dentition is—

$$i \frac{3.3}{1.1}; d m \frac{3.3}{3.3}; m \frac{1.1}{1.1} = 24;$$

the additional teeth being *i* 3 and *m* 1 (C, fig. 146), in which the demonstration of the true deciduous character of *d* 2 and *d* 3 is shown by the germ of their vertical successor *p* 3, which is exposed in the substance of the jaw. The next stage is the shedding of *d* 2, and the acquisition of *m* 2 (D, fig. 146). Then *d* 3 is shed by the ascent of *p* 3 into its place (E, fig. 146). Afterwards *m* 3 is acquired; and in the *Macropus gigas*, *p* 3, simultaneously pushed out (F, fig. 146).

Thus, four individuals of this species may be found to have the same number of molars, *i. e.* $\frac{4.4}{4.4}$; two of these individuals may seem, on a cursory comparison, to have them of the same shape, *e. g.*, as in C and E, fig. 146, or as in D and F. In fact, to determine the identity or difference in such instances, it requires that the substance of

Homologies of the Teeth.

the jaws be examined, to see if the germs of successional teeth be present, as at $p\ 3$, C and D, or at $m\ 3$, E. The result of such examination may be to show that not one of the four Kangaroos with the $m\ 4$ had the same or homologous teeth.

The four grinders, *e. g.* may be— $d\ 2$, $d\ 3$, $d\ 4$, $m\ 1$; as in C; or $d\ 3$, $d\ 4$, $m\ 1$, $m\ 2$; as in D; or $p\ 3$, $d\ 4$, $m\ 1$, $m\ 2$; as in E; or $d\ 4$, $m\ 1$, $m\ 2$, and $m\ 3$; as in F.

The changes, however, do not end here. As age advances, $d\ 4$ is shed, and the molar series is reduced numerically to the condition of B; but, instead of $d\ 4$, $d\ 3$, and $d\ 2$, it consists of $m\ 1$, $m\ 2$, $m\ 3$.

Finally, $m\ 1$ is shed, and the dentition is reduced to the same numerical state as at A; the teeth, however, being $m\ 2$ and $m\ 3$. The order here described is not precisely that which is followed in some of the smaller species of Kangaroo. In *Macropus Benettii*, *e. g.* the acquisition of $m\ 3$ is not accompanied by the displacement of $p\ 3$; and a molar series of $\frac{5}{2}$ is long retained.

These symbols, it is hoped, are so plain and simple as to have formed no obstacle to the full and easy comprehension of the facts explained by means of them. If these facts, in the manifold diversities of Mammalian dentition, were to be described in the ordinary way, by means of verbal phrases or definitions of the teeth, *e. g.*, the second deciduous molar representing the fourth in the typical dentition, instead of $d\ 4$, and so on, the description of dental development would continue to occupy much unnecessary space, and would levy such a tax upon the attention and memory as must tend to enfeeble the judgment and impair the power of seizing and appreciating the results of the comparison.

Each year's experience has strengthened the writer's conviction that the rapid and successful progress of the knowledge of animal structures, and of the generalizations deducible therefrom, will be mainly influenced by the determination of the homology of parts and organs, and by the concomitant power of condensing the propositions relating to them, and of attaching to them signs or symbols equivalent to their single substantive names. In the writer's work on the *Archetype of the Skeleton*, he has denoted most of the bones by simple numerals. The symbols of the teeth are fewer in number, are easily understood and remembered, and, if generally adopted, might take the place of names. They would then render unnecessary the endless repetition of the verbal definitions of the parts, harmonize conflicting synonyms, serve as a

universal language, and at the same time express the expositor's meaning in the fewest and clearest terms. The entomologist has long found the advantage of such

Homologies of the Teeth.

Development and Succession of the Molar Series, Kangaroo.

signs as ♂ and ♀, in reference to the sexes of insects, and the like; and it is hoped that the time is now come when the anatomist may avail himself of this powerful instrument of thought, instruction, and discovery, from which the chemist, the astronomer, and the geometrician have obtained such important results.

(R. O.)

Odryse
||
Æcolampadius.

ODRYSÆ, an important tribe of Thrace, occupied a territory whose limits were different at different times, but whose central part was on the banks of the Artiscus and in the neighbourhood of the Hebrus. They seem to have been a colony of that horde of barbarians that came pouring into Thrace from the north after the Trojan war. They were an important people from the first period of their settlement. Their name frequently occurs in legendary history. Thamyris, the ancient bard, is said to have been one of their tribe, and Orpheus is represented to have been their king. At the date of their introduction into authentic history, during the invasion of Scythia by Darius Hystaspis, their native mountains protected their independence against the Persians; and the fine breed of horses which they pastured on the plains of the Hebrus supplied their armies with a large and efficient squadron of cavalry. In the latter half of the fifth century B.C. they had extended their territory northward to the Danube, westward to Abdera, and eastward to the Euxine Sea; and their annual revenue had risen to be equal to the sum of 800 talents. The prosperity of the Odryse, however, had now reached its zenith, and began to decline. A disputed succession divided them into factions, and made them an easy prey for their ambitious neighbours. In 357 B.C., after a course of various fortune, the Athenians wrested from them the Thracian Chersonese; and in 343 B.C., after a war of nine or ten years, Philip II. of Macedon reduced them to the state of tributaries, and began to plant Philippopolis and other colonies in the very heart of the country. Yet the spirit of independence among the Odryse soon began to revive, and even before the death of Alexander the Great they had raised the standard of rebellion. On the accession of Lysimachus to the sovereignty of Thrace they commenced a struggle for liberty, which continued with various intervals till the fall of the Macedonian kingdom. The Odryse then became the auxiliaries of the Romans, and were employed in subjecting the other Thracian tribes to the dominion of Rome. Yet they retained a form of independence, and were treated like allies rather than tributaries. Augustus allowed them still to be governed by native sovereigns, even though their king Sadales, in 42 B.C., had bequeathed his kingdom to the Romans; Crassus bestowed upon them parts of the territory of the Bessi; and in course of time Rome had placed the whole of Thrace under their control. Yet in the time of Tiberius they began a series of rebellions, which resulted in the abolition of their independence, and the reduction of their territory into the form of a Roman province, during the reign of Vespasian.

ÆCOLAMPADIUS, the Græcized name of *Johann Hausschein*, one of the most eminent of the Reformers. He was descended by his mother's side from a Swiss family, and was born at Weinsberg in Franconia in 1482. His father, a wealthy merchant, at first intended him for trade, and afterwards sent him to Bologna to learn jurisprudence. But the timid youth, averse to the turmoil of business and fond of letters, soon entered upon the peaceful and studious life of an ecclesiastic. He studied divinity at Heidelberg, and Greek and Hebrew at Stuttgart; in 1516 he was preaching at Basle, and assisting his friend Erasmus in publishing *Annotations on the New Testament*; and in 1520 he retired into the monastery of Altenmünster, near Augsburg. Yet underneath this love of literary ease there was a strong sincerity of heart, which would not suffer him to remain undecided in the midst of the controversies of those reforming days. Before two years had passed, his attacks upon the creed of the Romish Church had brought him into danger: he escaped immediately from the convent, and took refuge in the castle of Ebernburg; and in 1524 he undertook the duties of a preacher and a theological professor at Basle, with the avowed intention of teaching nothing but what was consistent with the Scrip-

tures. From this period Æcolampadius was a learned, tolerant, yet decided advocate of the opinions of the Reformed in Switzerland. In a short time his elegant and powerful eloquence had overcome all opposition in Basle; and a thorough reformation of the church in that town was going rapidly on under his superintendence. He then went to the assistance of Zwingle in the controversy with Luther regarding the real presence in the Eucharist. A treatise, entitled *De vero intellectu verborum Domini "Hoc est Corpus Meum,"* was published by him in 1525; this was followed, as the controversy proceeded, by several letters and pamphlets; and in the celebrated discussion in 1529 at Marburg between the champions of the two parties, he entered the lists against the great German Reformer. He was still busily engaged both with tongue and pen in refuting the Lutherans, when death closed his career, in December 1531.

The principal works of Æcolampadius are—*In Librum Job Exegemata*—*In Daniele Prophetam Libri Duo*, fol. 1553; and *Commentarii Omnes in Libros Prophetarum*, in 2 vols. fol., 1558. His Life, written in Latin by Capito, and published in 4to, 1536, was translated into English, and printed along with those of Zwingle and Luther, by Henry Bennet Callesian, 8vo, London, 1561. There is also a Life, in German, by Herzog, in 2 vols., 1843.

ÆCUMENICAL COUNCILS. See COUNCIL.

OEDENBURG (Hung. *Sopron* or *Soprony*; anc. *Sempronium* or *Sopronium*), a town of Hungary, capital of a county of the same name, stands on the Ilkva, not far from the Neusiedlersee, 36 miles S.S.E. of Vienna. It is well built, and has the appearance of a quiet Austrian country town, with little of the Hungarian character about it. The watch-tower, which is all that remains of the old fortifications, is said to be the loftiest in Hungary. Some of the Roman Catholic churches are fine Gothic edifices; and there are also a Protestant church, a Dominican convent, a Ursuline nunnery, Roman Catholic and Protestant schools, orphan hospital, and theatre. Manufactures of woollen, linen, and cotton fabrics, potash, hardware, &c., are carried on; and the town has also sugar refineries and potteries. Some trade is carried on in these articles, as well as in the produce of the country; and large markets for cattle are held here, at which about 40,000 oxen and 160,000 pigs are sold annually. Many Roman antiquities have been found in the town. The inhabitants are mostly Germans, and about half of them are Protestants. Pop. (1851) 16,274.

The county of Oedenburg, which is bounded N.E. by Wiesselsburg, E. by Raab, S. by Eisenburg, W. and N. by the archduchy of Austria, has an area of 1272 square miles. It is occupied on the W. by low branches of the Styrian Alps, while towards the E. it is quite flat. Nearly the whole of Neusiedlersee is in this county, and it receives the most of the rivers. The soil is generally fertile, though swampy in some parts, and yields large crops of corn, flax, wine, and fruits. Live stock are reared to a considerable extent, and abundance of fish is obtained from the lake. Pop. 207,800.

ÆDIPUS, an ancient Grecian king, whose tragical sorrows were a favourite subject of the classical poets, was the son of Laius and Jocasta, the King and Queen of Thebes. The following is the ordinary account of the cruel destiny of his life. King Laius had been warned beforehand by an oracle that he should be slain by his son. Accordingly, no sooner was the infant born, than with his feet bored and bound together, he was carried away and exposed on Mount Cithæron. A shepherd chancing to pass that way, took him up and conveyed him to Polybus, the tyrant of Corinth. This king, being childless, adopted the infant, and seeing his little feet swollen, called him *Ædipus*. Years passed by; and the foundling was growing up at the Corinthian court a young man, and the reputed son of Polybus, when one

Æcumenical Councils
||
Ædipus.

Oehlenschläger.

day he heard his supposed parentage tauntingly questioned. This threw him into the torture of uncertainty, and hurried him away to consult the oracle of Delphi. The oracle would give no other response than the prediction that he should slay his father and marry his mother. Shuddering under the prophecy, Œdipus resolved to return no more to Corinth, and, led blindly on by Destiny, he bent his steps towards Thebes. On a narrow part of the road between Delphi and Daulis, a menial driving an elderly personage in a chariot called to him saucily to get out of the way. The insult was resented; a scuffle ensued; and the young traveller slew his two opponents. The elderly personage was Laius; and thus part of the horrible prediction had been fulfilled. Unconscious of what he had done, Œdipus held on his way; and arriving at Thebes, found the neighbourhood in a terrible dilemma. The Sphinx, settled upon a rock, was exacting, on pain of death, from all who passed by, an answer to a riddle; every one in turn was failing in the attempt to give a solution; and the population was fast wasting away before the clutches of the monster. At this juncture Œdipus solved the fatal enigma, and the Sphinx fell lifeless from her lofty seat. The hand of Queen Jocasta was bestowed as a reward upon the deliverer of the people; and thus the fulfilment of the predicted destiny was completed. Several years, however, passed before it was known. At length a plague fell upon the Thebans; the oracle declared that the calamity could only be stopped by the discovery of the murderer of Laius; the seer Tiresias made this discovery; and the revolting secret burst disastrously upon the royal family. Jocasta hung herself; Œdipus tore out his eyes. In course of time he wandered forth, led by his daughter Antigone, and after much travel, found himself near Colonus in Attica. Entering the unapproachable grove of the Furies, he remained there under the protection of these dread goddesses till his death. The history of Œdipus furnished the subject of several ancient tragic poems. The *Œdipus Tyrannus* and the *Œdipus Colonus* by Sophocles, and the *Œdipus* by Seneca, are still extant.

OEHLENSCHLAGER, ADAM GOTTLÖB, the greatest poet and dramatist of Denmark, was born at Westerbrø, a suburb of Copenhagen, on the 14th of November 1779. He was named after his father's patron, Count Adam Gottlob Moltke, who had secured for the elder Oehlenschläger the place of organist, and afterwards that of steward of the royal chateau of Fredericksborg. This palace, distant about two miles from Copenhagen, and built, it is said, after the design of Inigo Jones, was a favourite resort of the court in summer, but in winter was left to the solitary occupation of the poet's parents, two watchmen, and a couple of dogs. Here the boy grew up; and he was fond of recording in later years the delight with which he used to traverse the stately but deserted apartments, feeding his childish eye with gazing on the portraits of heroes and kings, and imagining for himself a brilliant future of fortune and fame. Here he acquired such rudimentary knowledge as the dame's school and the parish clerk could furnish, and he was allowed to read whatever came in his way, or could be found to his taste in a circulating library of the capital, to which he was permitted by his father to make exploring expeditions on fine days. His reading lay chiefly in romances, old and new. *Robinson Crusoe* and *Tom Jones* shared his favour with the *Arabian Nights* and *Siegfried the Dragon-Slayer*; and he knew the Comedies of Holberg, the German Molière, almost by heart. In boyhood, as in after life, he felt the beauties of nature deeply, and was quick in the perception of character. The beautiful suburb in which he lived a free and rambling life gratified his sense of natural beauty; and even in the narrow and homely circle of his father's friends he found scope for the exercise of his faculty of observation. The power of improvisation, and the impulse to convey his own ideas and impressions to

Oehlenschläger.

others, so often developed in boyhood and lost in after years, showed itself early in him; and before he was twelve years of age he was overheard by the clergyman preaching in the chapel to an imaginary audience with so much effect, that his unexpected auditor urged his parents to educate him for the church. To give him an education in the capital was, however, beyond his father's humble means. Fortunately for his future career, his talents attracted the notice of Edward Storm, the Norwegian poet, who procured his admission as a free scholar into the School for Posterity in Copenhagen, of which Storm was superintendent. Here the same activity of mind continued to be shown; but Latin and history suffered not a little beside the stronger attractions of poetry and the drama. Oehlenschläger's mind was not one to pursue any study with method, or to follow it into its depths. His curiosity and thirst for knowledge, always active, was quickly satisfied, and as quickly started off in search of some new object. As his boyhood advanced, the dramatic faculty became more developed. The characters he imagined, he was irresistibly compelled to embody and to put into action. Thus he used to write little pieces to be acted by himself and his playfellows, among whom he soon became a favourite and a leader. His facility of composition was even then remarkable. "My dear boy," Storm said to him once with quiet irony, "you are a greater poet than Molière. It used to be thought a feat in him to write and bring out a piece in eight days; you dash it off with ease in one." Storm, with whom he was a favourite, looked after his studies for three of the four years he remained at the Posterity School, when death deprived him of the poet's kind and thoughtful friendship. Oehlenschläger took a fair place among his fellow-students; and, despite his desultory habits and imaginative pursuits, he acquired during this period a fair knowledge of history, geography, and his mother tongue; he was well up in geometry and trigonometry, had mastered German, knew something of French, and had gained a superficial knowledge of some of the sciences. At the age of sixteen Oehlenschläger was confirmed, and left the school; and now the question arose, to what he was to turn? His father's scanty means made it important that the boy should be speedily put in the way of earning his own livelihood. Commerce was talked of; but a merchant without money was, as his mother said, like a violin without strings. Oehlenschläger, besides, knew nothing of English, then, as now, the great language of trade; and arithmetic had always been his stumbling-block. A vacancy, however, was heard of in the counting-house of a friend at Christianshafen, and thither Oehlenschläger, with a heavy heart, went with his father. To his infinite satisfaction they found that the young man whose place he was to fill had resumed his duties, and they had to return as they went. On the way back Oehlenschläger persuaded his father, whose disposition was easy to a fault, to allow him to prosecute at home the studies necessary to enable him to take his degree in arts. To these he applied himself for some time with zeal, taking lessons in Greek and Latin from the tutor of the sons of the gardener at Fredericksborg; but his progress in these severer studies was not great. The Muses continued to assert their mastery over him, and his scanty pocket-money was expended upon plays and visits to the theatre. Despairing of success in any other career, he determined to go upon the stage, for which he was in some measure prepared by his practice in the plays which he had been in the habit of performing with his companions. Having with some difficulty obtained his parents' consent to this step, and secured from the necessary authority an admission to the court theatre at Copenhagen, he made his appearance, after a course of preliminary study under the direction of Rosing, then the leading actor there. He continued on the Copenhagen stage for nearly two years; but his success was simply respectable, and

Oehlen-
schläger.

not such as to reconcile him to the difficulties and anxieties of a profession for which he had manifestly no peculiar vocation. His office was to write plays, not to act them. A variety of little circumstances combined to make his position in the theatre irksome. Rosing alone seems to have entertained hopes of him as an actor. This was not enough for Oehenschläger, and he threw up his engagement, after having remained on the stage just long enough to learn something of the technical requirements of the art for which he was afterwards to minister such admirable materials. About this time, too, he had made the acquaintance of the brothers Oersted, one of whom afterwards married his sister. Their habits of methodical and profound study impressed him deeply. He had seen nothing like it before, and, contrasting their attainments with his own, he was stimulated to retrieve, if possible, the time which he had lost. To this he was encouraged by these gifted brothers; and, under the guidance of Anders Sandøe Oersted, he devoted himself for a time with ardour to the study of jurisprudence, and passed the preliminary examinations with credit. Oehenschläger was still only nineteen, and his poetic powers had been quickened into action by the loss of his mother, whom he loved tenderly and deeply, and by an attachment which he formed for his first and only love, Christiana Georgina Elizabeth Heger, the daughter of the Counsellor Heger. Literature soon divided his attention with the studies of law. He read much, especially in the authors of the great German school, which had recently sprung up; and his writings, both in verse and prose, began to attract attention. He associated with men of letters, and gave much attention to the study of northern antiquities, mythology, and literature. The expedition of the British fleet against Copenhagen for a time interrupted these peaceful studies. Oehenschläger joined a corps of volunteers, and has left an amusing account of their amateur military career. This temporary distraction over, he returned with renewed activity to his former literary pursuits, and in 1803 published his first volume of poetry. Some of its contents are worthy of his subsequent fame; but it was not until the appearance of his dramatic poem of *Aladdin* in 1804 that he gave the assurance of realizing the boast with which, in a moment of enthusiasm, he had on one occasion startled and amused his companions, that he would one day rescue Danish poetry from the decay into which it had fallen since the days of Ewald. This work bears the unmistakeable impress of genius. The luxuriance of fancy, the freshness and exuberance of feeling, the variety and truth of the characters, the spontaneousness of emotion, and the pervading sense of power, reconcile the reader to its want of compression and occasional feebleness of execution. All the wealth of a lively and sensitive nature is scattered lavishly over its pages. In the composition of this work Oehenschläger felt that nature had destined him for a poet, and not for a lawyer. His countrymen took the same view; and, through the interest of Count Schimmelman, he obtained from the Danish government a travelling pension in August 1805. With this he made a tour through Germany, where he made the acquaintance of Goethe and Wieland, and the brilliant circle whom the old Duchess Amelia had gathered around her at Weimar. At Halle he wrote his *Hakon Jarl*, his second play, in six weeks. At Goethe's suggestion he translated the *Aladdin* into German, and he dedicated his translation to that poet in lines of great beauty. He followed the same course with reference to all his principal plays, revising as he translated them, so that they frequently appear to more advantage in their German than in their Danish dress. From Weimar he went to Paris, where he wrote his *Palnatoke*, and *Azel und Walburg*, dramas unsurpassed by any of his later works. Here, too, he conceived the idea of his *Correggio*, the first and best of the long line of

Oehlen-
schläger.

art-dramas in which Germany has since been prolific, although it was in Parma that this fine work fitly took a definite shape, which was afterwards perfected in Rome. After an absence of five years, Oehenschläger returned in 1810 to Copenhagen, where he was already famous, and an enthusiastic reception awaited him. He had endowed some of the finest national legends with a noble dramatic life, and laid the foundation of a national drama of the best kind. His countrymen were proud of him, and at this early period, as through all the rest of his long life, were not sparing in their demonstrations of regard. He was appointed professor of æsthetics at the university of Copenhagen,—a position which he continued to fill with honour till nearly the close of his life. On the 10th of May 1810 he married Christiana Heger, to whom he had been so long betrothed, and whom, after the companionship of many years of uninterrupted happiness, he lived to regret. From the time of his return to Copenhagen, Oehenschläger's life was one unbroken career of literary labour and of literary honour. He wrote much in nearly all departments of the belles lettres,—poems, dramas (serious and comic), operettas, tales, and novels. It is by his dramas, however, that posterity will know him. Besides comedies and operas, he wrote twenty-four tragedies, of which nineteen are on Scandinavian themes. These are of various and unequal merit; but all are more or less deserving of perusal, and some will rank among the first in the first class of modern dramas. Like all dramatists of the highest order, Oehenschläger himself is not seen in the best of his works. His characters feel and speak with a spontaneousness, and truth to the situation, which make the reader forget the author in the living reality of the scene. The art to blot, however, was one which Oehenschläger seems never to have learned. As the first impulse came, so he wrote; and his writings accordingly bear many traces of feebleness, which a more vigorous judgment would have been at pains to remove. Oehenschläger was scarcely less esteemed in Sweden than in Denmark. In the summer of 1829 he visited that country, where he was greeted by all classes with a burst of enthusiasm such as commonly is bestowed only on conquerors or kings. He was met on the high road by a procession of students. Addresses were presented to him from all quarters. At the distribution of degrees in the ancient cathedral of Lund, Bishop Tegnér, the greatest poet of Sweden, saluted him with a panegyric in hexameters in which he was hailed as the king of the poets of the north, and placed a laurel crown upon his head amidst a storm of music and artillery. Soon afterwards he was made a knight of the North Star by the King of Sweden, and received the diploma of doctor of philosophy from the university of Lund. Ovarations not less gratifying awaited him on a subsequent visit to Sweden, and also to Norway. In 1815 he received from the King of Denmark the knighthood of Dannebrog, and in 1839 he was appointed counsellor of state. Other and higher honours were subsequently conferred upon him in his own country; and from the sovereigns of Sweden, Prussia, and Belgium he received similar distinctions. A great festival was held at Copenhagen on the 14th November 1849, in honour of his seventieth birthday, on which occasion he recited a poetical address, in which he said,—

"Although the end far distant may not be,
There's life and sinew in the old man yet;
To you I drink, and drain the cup with glee,
'For 'tis no funeral feast that here is set."

He was then in the full enjoyment of all his powers, and was even then busy with literary tasks. But about six weeks afterwards symptoms of a breaking up of the constitution appeared; and he died on the 20th of January 1850. About an hour and a half before his death he requested his son to read to him that part of the scene in the fifth act of his tragedy of *Socrates*, where the philosopher speaks of death.

Oels
||
Oeniadæ.

"It is," he said, "so unspeakably beautiful." He heard the passage read with deep emotion, "and with a smile," says the biographer, "of rapturous delight. When it was concluded, he put an end to the reading, and took leave of his family." The incident is characteristic, not, as has been said, of the poet's vanity, but of his simple faith, which regarded himself only as the medium through which an inspiration from a higher source spoke. So it was with Oehlenschläger through life. His poetry flowed from him under an inspiration as unconscious, and often as fitful, as music from the wind-swept chords of an Æolian lyre. When the mood passed, he seems to have rarely set himself to the task of rejecting what was weak or indifferent, or heightening by the touches of art what had been left imperfect in the heat of composition. Oehlenschläger's death was felt as a national loss, and his obsequies were celebrated with almost regal honours. A funeral oration was pronounced over his remains by the Bishop of Seeland in the cathedral of Copenhagen, and they were then borne to the church of Fredericksborg attended by a crowd of more than 20,000 people, or about a sixth of the entire population of the capital. The prince royal, the royal aides-de-camp, the whole diplomatic body, all the clergy, and the different guilds of arts and manufactures, swelled the train; and the coffin was borne by the youth of the public schools. Thus royally attended, the great Scandinavian bard was laid to rest in the grave of his fathers on the 26th January 1850.

Oehlenschläger was robust in body as in mind,—a burly man, with a large head, and features which beamed with intelligence and vivacity. He seemed to be rather a child of the sunny south than of the north. His complexion was tinged with ruddy bronze, his eyes were dark and brilliant, his smile full and joyous, his gestures animated and quick. His sensibilities were at all times readily moved. He enjoyed keenly, and his sympathies were wide and genial. There was to the last much of the child in him; and in the midst of their admiration his friends were often moved to smile at his harmless egotism. Rarely has a poet's life been happier, or more in harmony with his nature. Born poor, he was fortunate in the love of parents with whom he grew up in an atmosphere of simplicity, integrity, and piety. He was fortunately enabled by well-timed patronage to follow from the first the instincts of his genius. His country early recognised his claims. Placed by it in a position to pursue his literary career without anxiety, he was cheered through life by the assurance that his efforts were watched with interest, and welcomed with hearty sympathy. Rich in purse he never was; but he was rich in the love of a wife to whom he was devoted, and of children who caused him no regrets,—rich in the possession of all his powers of mind and body to the close of a long life,—rich in the love of honoured friends, and in the admiration of his country. In him genius was happily allied with goodness; and the world dealt kindly with the man whom nature had endowed with many of her choicest gifts. (T. M.—N.)

OELS, a town of Prussia, in the government of Breslau, on the Oelsa, 17 miles N.N.E. of Breslau. It is fortified; and has an extensive ducal palace built in the form of a square, and containing a good library; a Roman Catholic and three Protestant churches, a synagogue, several schools, an hospital, and a theatre. Manufactures of woollen, linen, and silken stuffs are carried on here; and there are oil and other mills. Pop. 6928.

OENIADÆ (modern *Trihardo*), an important town of Acarnania in ancient Greece, was situated on the western bank of the Achelous (*Aspropotamo*), about 2 miles from the mouth of that river. Its name was probably derived from Cæneus, a legendary Ætolian hero. It stood on an insulated hill, strengthened by massive walls, and surrounded on all sides by extensive morasses. These fortifications, natural and artificial, rendered the town for a considerable time a formidable and invincible foe to the

Oenotria
||
Offenbach.

Athenians. Pericles was unable to take it by siege in 454 B.C.; Phormion advanced against it in 429 B.C., but could not pass across the swamps; and it was not until 424 B.C. that it was forced by the general Demosthenes to take the Athenian side in the Peloponnesian war. This seems to have been a fatal blow to the independence of Cæniadæ. In the latter half of the fourth century B.C. it was taken by the Ætolians; in 219 B.C. it passed into the hands of Philip, King of Macedonia; and in 211 B.C. it was captured by the Romans, and given once more to the Ætolians. Although the citizens were freed from the dominion of their fellow-countrymen in 189 B.C., they never recovered their former importance. From that date Cæniadæ disappeared from the arena of history. Large portions of its walls still remain in excellent preservation.

OENOTRIA. See ITALY.

OEERSTED, HANS CHRISTIAN. See DISSERTATION SIXTH, chap. vii., sec. 4.

OESEL, an island belonging to Russia, stretches across the mouth of the Gulf of Riga, between N. Lat. 58. and 58. 40., E. Long. 21. 40. and 23. 20. Its length from S. by W. to N. by E. is about 45 miles; average breadth, 12 miles; area, about 1200 square miles. Next to Zealand, this is the largest of the islands in the Baltic. It has steep and bold coasts, and a rocky undulating surface, watered by numerous streams. The rocks are for the most part calcareous; and the soil, though not naturally fertile, may be made productive by means of manure. A great part of the island is covered with forests, and a considerable extent of it is used as pasture ground. The climate is milder in winter than that of the adjacent mainland; but in spring and autumn severe storms frequently occur. Corn is raised in sufficient quantities to furnish an article of exportation; wheat, rye, barley, and oats being the principal crops; while hemp and flax are also cultivated. Many of the inhabitants are also employed in pastoral and piscatorial pursuits. Few manufactures are carried on. The majority of the people are Lutherans; and the chief town is Arensburg, on the S.E. coast. Cesel at one time belonged to the Teutonic knights, but was seized by the Danes at an early period, and ceded by them to Sweden in 1645. In the beginning of the eighteenth century it was taken possession of by Russia, to which power it was finally ceded in 1721 along with Livonia, of which government it forms a part. Pop. about 40,000.

OETINGER, FRIEDRICH CHRISTOPH, a mystic divine, was born in 1702 at Göppingen in Würtemberg. After finishing his education at the university of Leipsic, and occupying himself with several learned engagements, he was appointed pastor at Hirschau in 1738. It was about this time that he began to imbibe the doctrines of mysticism from the treatises of Boehmen and others. In 1765 his edition of the works of Swedenborg, in 2 vols. 8vo, and his treatise entitled *Earthly and Heavenly Philosophy*, revealed his opinions to the public, and drew down upon him the reprehension of his ecclesiastical superiors. Yet protected by the Duke of Würtemberg, and aided by his own excellent character, he rose to a high position in the church. After passing through several grades of promotion, he was appointed prelate at Murhard, and continued there till his death in 1782.

OFANTO (anc. *Aufidus*), a river of Italy, in the Kingdom of Naples, rises in the Apennines, province of Principato Ultra, flows E.N.E., separating Capitanata from Basilicata and Bari, and falls into the Adriatic, after a course of 75 miles. On the right bank is the field of the battle of Cannæ, where the Romans were totally defeated by Hannibal, B.C. 216.

OFFENBACH, a town of Hesse-Darmstadt, province of Starkenburg, on the left banks of the Main, here crossed by a bridge of boats, 5 miles E.S.E. of Frankfort. It is well

Offenburg built and partly walled; and has a ducal palace, several churches, a school, poor-houses, theatre, &c. Its manufactures are extensive, consisting of woollen, cotton, and silken fabrics; gloves, wax-cloth, leather, soap, earthenware, &c. There are no fewer than ninety-five manufacturing establishments in the town, employing 6000 hands, and producing annually about L.650,000 worth of goods. This place is also remarkable for its bookbinding, in which art it is superior to any other place in Germany. An active trade is carried on in wine and other articles. Pop. (1852) 13,087.

OFFENBURG, a town of Baden, in the circle of Mittelrhein, on a hill near the Kinzig, 42 miles S.S.W. of Karlsruhe. It has a town-house, merchants' hall, school, nunnery, hospital, &c. Manufactures of leather, glass, and other articles, and some trade, are carried on. Pop. 4010.

OFFICINAL, is the name applied to such medicines, whether simple or compound, as are required to be constantly kept in the apothecaries' shops.

OGDENSBURG, a town of the United States of North America, state of New York, on a plain at the confluence of the Oswegatchie with the St Lawrence, 200 miles N.N.W. of Albany. It is well and regularly built; and contains numerous churches, belonging to Presbyterians, Episcopalians, Methodists, Baptists, and Roman Catholics; an academy; and three banks. There are iron-foundries, machine-shops, and other manufactories. The trade of the town is considerable; and it communicates by steam-vessels with the different ports on Lake Ontario. It is also connected by railway with Boston and New York. The number of vessels that entered the port in 1852 was 830; tonnage, 347,698; that cleared, 798; tonnage, 341,183. Pop. (1853) about 6500.

OGECHEE, a river of the United States of North America, state of Georgia, flows S.E., and falls into the Atlantic by Ossabaw Sound, 20 miles S. of Savannah. Its whole length is 250 miles; and it is navigable by sloops for 30 or 40 miles.

OGILVY, JOHN, an industrious author and literary speculator, was born at Edinburgh in 1600. His father was a prisoner for debt in the King's Bench, and could give him but little education. Yet the boy had a practical ingenuity, and an ever-wakeful prudence which led him over the greatest difficulties on towards success. While supporting himself by teaching dancing to the families of the English nobility, he contrived to gratify his eager avidity for learning. In 1649 his literary accomplishments had become so considerable that he became an author by profession, and began to publish a series of metrical translations of some of the ancient classics. His *Virgil* appeared in that same year, his *Fables of Æsop* in 1651, his *Iliad* in 1660, and his *Odyssey* in 1665. Yet although Ogilvy had gained distinction by these publications, and although he had been appointed superintendent of the poetical part of the coronation pageantry in 1661, and master of the revels in Ireland in 1662, he continued to be the same plodding and practical man of business. After the great fire of 1666 had reduced him to beggary, he contrived in a short time to set up a printing-press; and in the capacity of cosmographer to the king, published a large atlas in several folio volumes, and a description of the roads in England from his own actual survey. His death took place in 1676.

OHIO, one of the United States of North America, situated on the river of the same name, which separates it on the S. and S.E. from Kentucky and Virginia; on the E. it has Pennsylvania; N., Lakes Erie and Michigan; and on the W., Indiana. It has an area of 39,964 square miles, being somewhat greater than that of the kingdom of Portugal; and, in all respects, it is one of the most important states of the valley of the Mississippi or of the American Union.

VOL. XVI.

The face of the country is delightfully varied, and presents a table-land from 600 to 1000 feet above the level of the sea. A ridge of high lands divides the waters flowing north into Lake Erie from those flowing south into the Ohio. There is a ridge crossing the state in the latitude of Columbus, south of which the surface is diversified by hills and valleys. Swamps and morasses occasionally occur, forming, however, only a twentieth part of the whole surface. The river-bottoms are extensive and very fertile. Prairies are numerous; but the country was originally covered with magnificent forests, which are still far from being extinct.

The Ohio River and Lake Erie receive the waters of the state. Those streams which enter into the Ohio are the Muskingum, Hockhocking, Scioto, Miami, &c. The Muskingum is navigable 75 miles for steamers, and for small boats nearly to its source. The Hockhocking courses through a hilly and beautiful country, and is a deep and narrow stream. The Scioto can be ascended to nearly its source, and has many thriving towns on its banks. Its valley is wide and fertile. The Little Miami is less adapted to navigation than to mill-sites. The Big Miami enters the Ohio in the S.W. corner of the state, after a course of 100 miles. The northern rivers are the Maumee, Sandusky, Cuyahoga, which are in part navigable, but furnish the most abundant water-power for manufacturing purposes. The other streams are the Portage, Black, Rocky, Vermillion, &c.

Over nearly the entire surface of the state there lies a deposit of various thickness, known by the name of alluvium, believed to have been made by currents of water. One of the most important strata is a transition limestone, equivalent to the mountain limestone of Europe. It crops out in places, forming, at small cost, a valuable building material. East of the Huron and Olentangy rivers the lime stratum dips under one of shale or clay-slate; farther east this passes under a stratum of sandstone; still farther, the sandstone is overlaid by a conglomerate, and then by the lower coal series; and, finally, the upper coal series passes beyond the eastern and south-eastern boundary of the state. One-third of Ohio is therefore within the great coal basin, of which Wheeling, Virginia, is the centre. In several of the southern counties are extensive beds of the best iron. In Western Ohio are found gypsum, salt, and lead. It is estimated that the beds of workable coal would be sufficient to last 10,000 years, supposing Ohio to use as much as is now used in England and Wales. By the census of 1850, it appears that Ohio produced as follows:—

	Establishments.	Capital.	Value of products.
Pig iron.....	35	L.313,123	L.261,632
Iron castings.....	183	429,923	639,444
Wrought iron.....	6	31,331	26,632
Salt.....	32	39,320	27,558

The county of Tuscarawas is 550 square miles in extent, and in every part of it, it is said, coal may be found. Professor Mather, in his report on the geology of the state, estimates the quantity of coal in this county alone at 80,000 millions of bushels! In 1840 the production of coal in Ohio is stated at 2,382,368 bushels, in 1848 at 6,538,968, in 1857 at 40,000,000 bushels; and the production of iron has swelled to the aggregate of 100,000 tons. The coal is bituminous. A belt of ironstone, averaging 12 miles in width, is 100 miles or more in length. Salt springs are numerous, and salt-works are frequent and successful. Marble, freestone, and gypsum occur.

Ohio is noted for the fertility of its soil. Where the transition lime rock is the upper stratum, as it is in nearly half the state, the soil is remarkably adapted to wheat and grass; and, indeed, seven-eighths of the state are considered well adapted to the growth of wheat. What is known as

- Ohio.** the Connecticut Reserve, having a shale and sandstone basis, is less fertile, yet producing fruits and grains suitable to the climate. About 25,000,000 acres of land in the state could be brought into cultivation, and would support many millions of inhabitants.
- Climate.** On account of its elevation, the climate of Ohio is several degrees lower in average temperature than on the same parallel in the Atlantic states. The summer is subject to tornadoes, but the autumn is always serene and pleasant, though the winters are occasionally severe. Along the valley of the Ohio the temperature is milder than in the interior, but fever and agues prevail to some extent in this section. The climate otherwise is very healthy,—as much so as that of the majority of the states.
- Forests.** In the forests are found black walnut, oak, hickory, sugar and other maple, beech, poplar, ash, sycamore, papaw, buckeye, cherry, dogwood, elm, hornbeam. The cypress is almost the only evergreen, and it is but scanty. Medicinal roots, such as ginseng, valerian, columbo, snake-root, blood-root, &c., are found. Fish and game are abundant.
- Agriculture.** At the last federal census (1850), it appeared that there were in Ohio 143,807 farms, having under cultivation about 10,000,000 of acres, with about 8,000,000 more inclosed, but unimproved. The average number of acres to each farm was 125; average value of farm, L.518; and of farming implements, L.37. Gross value of all the farms in the state, with their implements and machinery, L.77,500,000. The number of horses, asses, and mules, was 466,820; milch cows, 544,490; working oxen, 65,381; sheep, 3,942,929; and swine, 1,964,770. The total value of live stock was L.9,192,027; of animals slaughtered, L.1,549,839. The quantity of wheat raised was 14,487,351 bushels; of rye, 425,918; oats, 13,472,000; Indian corn, 59,078,695; potatoes, 5,245,760; barley, 212,440; buck-wheat, 638,060; hay, 1,443,142 tons; maple sugar, 4,588,000 lb.; tobacco, 10,454,449; wool, 10,196,371; silk cocoons, 1552; and wine, 11,524 gallons.
- Only another of the United States exceeded Ohio in the production of wheat. The other agricultural products are hops; clover and grass seed; pease and beans; market, nursery, and orchard products; flax seed, flax, and hemp. The produce of the vineyards is large, and commands a market in all parts of the Union.
- Manufactures.** Ohio, in the possession of coal and iron, may be said to have few rivals in capacity as a manufacturing state, when the full fruition of her reasonable hopes are realized. In 1850, she manufactured cotton goods to the value of L.231,452; pig-iron to about the same amount; castings, L.639,435; wrought-iron, L.26,632. She distilled or brewed nearly 100,000 barrels of ale, and 12,000,000 gallons of whisky, &c. The gross statistics of all the manufactures are as follows:—Establishments, 10,622; capital, L.6,045,733; raw material used, L.7,224,586; hands employed, 51,500; wages paid, L.2,805,758; annual product, L.13,051,507.
- Commerce.** Ohio being an inland state, must show very low figures in the foreign commerce of the Union. For the inland or home trade she enjoys advantages on account of her position with reference to the Ohio, the Mississippi, and the lakes, together with her great works of internal improvements, enjoyed by few, if any, of the other states. One of her leading authorities says, at the close of 1857, that her production of corn has reached to 90,000,000 bushels, and of wheat to 22,000,000. He estimates the total agricultural, mining, and manufacturing produce of Ohio for that year at L.40,800,000; and says that Ohio is now worth L.200,000,000, and that three-fourths of it have been made out of the profits of labour applied in the industrial pursuits. She exports L.12,500,000 of products, besides enjoying the commerce of her neighbours.
- The annual statement of commerce, published at Cincinnati, shows that the total produce received at that city in 1856-57 reached L.16,060,444; and that the exports were L.11,800,447. In the city and vicinity 500,000 barrels of whisky are distilled, consuming 8,000,000 bushels of corn and other grain. Number of hogs packed, 344,512. The city is increasing as a wheat, flour, and tobacco mart. Over 500,000 gallons of wine are produced from the vineyards in the vicinity, giving employment to a large number of persons, and producing large returns to capital.
- The Ohio Canal was completed in 1832, from the Ohio River to Lake Erie, 307 miles. Its branches or feeders are,—the Columbus branch, 10 miles in length; the Lancaster branch, 9 miles; the Athens extension to Hocking, a prolongation of the Lancaster, 56 miles; the Zanesville branch, of 14 miles, connects the Ohio Canal with the Muskingum improvement, by which another channel is opened to the Ohio River at Marietta; the Walhonding branch is 25 miles in length.
- The Miami Canal connects Cincinnati with Lake Erie, 270 miles, and was completed in 1832, with several branches. The whole number of miles of canals constructed by the state is 827, at a cost of over L.3,000,000. The other canals, which are private property, are the Sandy and Beaver, 76 miles, extending from the Ohio Canal to the Ohio River, at the mouth of the Beaver; the Mahoning Canal, 77 miles. The canals have, however, in part yielded to the railroads, and are in general far from being works of the first class.
- The oldest railroads are the Little Miami, from Cincinnati to Springfield, 84 miles; the Mad River, from Lake Erie to Springfield, 134 miles; the Mansfield and Sandusky; the Lake Erie and Kalamazoo, from Toledo, on Lake Erie, to Adrian, forming a junction with the Michigan Southern Road, to which it forms an outlet to the roads of Ohio, 35 miles. It would occupy too much space, however, to enter into a detail of the numerous railroad routes now in operation in Ohio. They constitute several great lines, running through the States from east to west, and from north to south, bringing nearly every county and town in its limits within reach of railroad improvement. Perhaps one of the most important of all these great works is the Ohio and Mississippi Railroad, 330 miles in length, which has been lately completed, and connects by a direct route the cities of Cincinnati and St Louis. The railroads in progress or in operation in Ohio, at this time, make up an aggregate length of 3000 miles; the surface of the country being most favourable to their construction. There are no lines of pre-eminent importance, because it is said that trade and commerce are not, as in other states, forced into peculiar channels by the natural configuration of the country.
- Among the cities are Cincinnati, which is known as the "Queen of the West," supposed now to have a population of over 200,000, making it the fifth city of the American Union; Columbus, the capital of the state, is the centre of a rich country, which is daily adding to its opulence and extent; Dayton is at the meeting of various railroad lines, and is therefore accessible from every point; Zanesville, on the Muskingum, is in the midst of a rich and populous valley region; Chillicothe, on the Scioto, is inclosed by picturesque hills; Springfield is at the junction of the Mad River and Lagonda Creek, which affords every variety for mill-sites; Stenbenville and Portsmouth are on the Ohio; Sandusky city is on Lake Erie; and Toledo on the Maumee River, at the terminus of the Wabash and Erie Canal.
- The amount appropriated for schools in Ohio from the several state funds reached, in 1855, L.544,540. The whole number of common schools was 12,012; number of scholars attending, 357,547 males, and 311,477 females. Total number of school-houses 7880, which had been erected at a cost of L.464,561. There are 91 high schools,

Ohio. having about 4000 scholars ; and 88 schools for coloured children, with about the same number of attendants. There were also a large number of German schools, adapted to that class of population.

Twenty-six daily newspapers were printed in 1850, 10 tri-weekly, 201 weekly; total of all classes, 261, printing annually 30,447,407 copies. The total number of libraries, other than private, was 352, having 186,828 volumes. The whole number of paupers reported was but 1673.

There is a lunatic asylum at Columbus, which had at the last statement 261 inmates. Two other institutions of like character have been opened at Newburg and Dayton. The Ohio penitentiary at Columbus has about 600 inmates. A library and schools are attached to the prison, and the convicts are instructed in the elementary branches. The state derives a small revenue from the institution. There is a deaf and dumb asylum, with 148 occupants; and a blind asylum, containing 72.

The value of church property in Ohio, by the census of 1850, was L.2,413,812, and the number of the church sittings was 1,457,769; the Methodist being the predominating sect, giving, with the Baptists, one-half of the whole number of seats.

There were, in 1850, 26 colleges, with 3621 pupils; 206 academies and private schools, with 15,052 pupils; 66,020 persons in the state over twenty years of age were incapable of reading and writing, or about 3 per cent. of that class, which compares very favourably with other western states.

Revenue. The total revenue of the state of Ohio in the year ending with January 1856 was L.756,492, and the expenditure L.731,681. The state cannot, by its constitution, contract debt for internal improvement. Total debt in 1856, L.3,390,334; value of the real estate at the same time, L.120,387,191; and of the personal estate, L.58,962,250. Total taxes of all sorts, L.1,765,520.

History. After the western exploration of Marquette (1673) from Canada, and the expedition of D'Iberville to the mouth of the Mississippi and up its stream, the French began the construction of forts throughout the extensive region which they embraced. Thus was founded their claim to Ohio; whilst the English, on the other hand, claimed it from grants made by their crown, which extended from sea to sea, and from a cession made by the six nations of Indians, who claimed the entire sovereignty of the Ohio valley. The English Ohio Company having made a settlement on the Great Miami, it was destroyed by the French in 1752, at which time war occurring between the two nations, many hostile expeditions were conducted with different results. The defeat of Braddock was followed by the victories of Dunmore. On the return of peace in 1763, the whole of Canada was ceded to England, and with it all the territory to the east of the Mississippi River. After the War of Independence the whole of the western lands held by the several states were ceded to the federal government. Surveys and sales of these lands being at once made, the Ohio New England Company purchased a tract lying adjacent to the Scioto and Muskingum rivers, where, in 1788, Marietta was begun, the first permanent settlement in Ohio. Governor Arthur St Clair was appointed territorial governor.

In 1787 John Cleves Symmes purchased from Congress a million of acres in Ohio, northward from the Ohio River, and between the two Miamis, in which region was founded the second settlement at Columbia, about five miles distant from the present city of Cincinnati. Mathias Denman purchased for 500 dollars the site on which Cincinnati is built, and the first cabin was erected in 1788. Other settlements immediately followed. The Indians, in despite of all treaty stipulation, continued to harass the settlers. Block-houses were constructed; and in 1789 Fort Wash-

ington, as a means of protection, was begun. These aggressions continuing, General Harmar, with 1300 men, marched against the Indian towns, but was compelled to retreat. In 1791 General St Clair, at the head of an army of 3000 men, undertaking a similar enterprise, was attacked by a combination of nearly all the north-western tribes, and after a gallant struggle, sustained a most disastrous defeat. The result of those reverses was severely felt in the settlement, and for some time the tide of emigration actually ceased. In 1794 General Wayne assembled an army at Greenville, and soon obtained a decisive victory over a force of 2000 warriors, at the rapids of the Maumee. Not until the country was laid waste, and forts on every hand were seen springing up, did these hardy warriors abandon their futile struggles. "When we consider," says an authority, "the fierce and unrelenting warfare waged by the Indian tribe upon the white settlements of the West, during thirty-seven years of almost uninterrupted conflict from 1757, when the first white man was killed in Kentucky, down to the period of Wyne's victory, we may form some faint idea of the toil and perils and sufferings of the bold and hardy race of the pioneers who effected the colonization of the Western World. An Indian chief, at the conclusion of a treaty yielding up the right of soil in Kentucky, said to Boone,—'Brother, we have given you a fine land, but I think you will have trouble to settle it;' and his prediction was fully verified there and elsewhere."

Constant streams of population began now to pour into Ohio. Connecticut sent many to her reserved tract bordering on Lake Erie. In 1798 the inhabitants of the territory numbered 5000, with eight organized counties. The first meeting of territorial legislature was held in September 1799. William Henry Harrison, then secretary of the territory, and afterwards president of the United States, was at that time elected to Congress. In 1802 the federal government authorized a convention to form a state constitution. It sat at Chillicothe; and Ohio was admitted into the Federal Union soon after. The first legislature met in the same place in 1803; and two years later the United States acquired, by another Indian treaty, the reserve west of the Cuyahoga River, and subsequently the Maumee and Sandusky region. In 1811 the Indians were defeated by General Harrison at Tippecanoe; and in 1816 the seat of government was removed from Chillicothe to Columbus, where it now is.

POPULATION.						
	1800.	1810.	1820.	1830.	1840.	1850.
Whites...	45,023	228,861	576,572	928,329	1,502,122	1,950,050
Coloured	337	1,899	4,862	9,574	17,345	25,279
Total.	45,365	230,760	581,434	937,903	1,519,467	1,980,329

Density to the square mile in 1840, 38.02; 1850, 49.55. Of the total population, but 1,219,452 were born in the state, and 538,134 in the other American states; and 218,312 were born in foreign countries. Of these, about 120,000 were of German origin.

OHIO, a river of the United States of North America, is formed by the confluence of the Alleghany and Monongahela, which rise in the Alleghany Mountains, and unite at Pittsburg, in the west of Pennsylvania. It then flows generally towards the S.E., separating the states of Ohio, Indiana, and Illinois, on the right, from those of Virginia and Kentucky, on the left; and falls into the Mississippi 1216 miles above its mouth; N. Lat. 37., W. Long. 89. 10. Its whole length is more than 950 miles; but its length in a straight line is not more than 614. At the confluence of the two great branches, the Ohio is somewhat more than 600 yards wide, and it immediately assumes that broad, placid, and beautiful aspect which it maintains to its

Ohlau
||
Oils.

junction with the Mississippi. Its breadth varies exceedingly, being in some parts 1400 yards, whilst in others it is only 400 yards across. Between Pittsburg and its mouth it is diversified with about 100 considerable islands, besides a great number of tow-heads (or barren sandy islands overgrown with willows) and sand-bars, which in low stages of the water greatly impede navigation. Some of these islands are of exquisite beauty, and afford most lovely situations for retired farms. The passages among them, and the sand-bars at their head, are great difficulties in the navigation of the river. Notwithstanding these obstacles, however, it is well adapted for boat navigation, the current being remarkably smooth and gentle, excepting at Louisville in Kentucky, where it is broken by falls, the water running for several miles with great rapidity, although not so much so as to be insurmountable by boats. A canal round these falls, a work of great magnitude and utility, has been completed. The annual range of the Ohio, from low to high water, is about 50 feet; the extreme range is 10 feet more. When lowest it may be forded at several places above Cincinnati. Throughout the year it is subject to sudden and very considerable elevations and depressions. Generally, the navigation is obstructed by floating ice for five or six weeks in winter. When the river is at its mean height, its current is about 3 miles an hour; when higher and rising it is more; and when very low it does not exceed 2 miles an hour. The Ohio and all its tributaries cannot, it is believed, have less than 5000 miles of waters navigable for boats; and taking all circumstances into account, few rivers in the world can vie with it, either in utility or beauty. From its very commencement it affords most delightful prospects. Rivers of a romantic and beautiful character flow into it almost at equal distances, like lateral canals. The aspect of the country on the banks has much grandeur, softness, and variety. Of the rivers and creeks which join it, the following are all navigable by steamboats for considerable distances, viz., the Muskingum, Great Kanawha, Big Sandy, Scioto, Miami, Kentucky, Green, Wabash, Cumberland, and Tennessee. The last is by far the largest and most important tributary of the Ohio, watering considerable portions of Alabama, Tennessee, and Kentucky. Of creeks and smaller rivers there are probably nearly two hundred which enter the Ohio; but a list of them would only be a dry catalogue of uncouth names. The area watered by the Ohio and its affluents is estimated at 200,000 square miles.

OH LAU, or **OLAÜ**, a town of Prussia, province of Silesia, government of Breslau, on the right bank of the Ohlau and left of the Oder, 18 miles S.E. of Breslau. It has a large castle, several churches, an orphan hospital, and a poor-house. There are extensive tobacco manufactories and a flour-mill, besides breweries, distilleries, &c. Pop. 6079.

OHRDRUF, a town of Saxe-Coburg-Gotha, in the principality of Gotha, on the Ohra, 8 miles S. of Gotha. It has a castle, a newly-erected town-hall, and several churches and schools. Manufactures of woollen cloth, porcelain, organs, &c., are carried on here; and there are also numerous mills and bleach-works. The trade is considerable in wool, coals, &c. Pop. 4559.

OICH, **LOCH**, a lake of Scotland, county of Inverness, between Loch Ness and Loch Lochy. It is about 4 miles in length by $1\frac{1}{2}$ in breadth; it receives the Glengarry River, and discharges its waters by the Oich into Loch Ness. This loch is connected by the Caledonian Canal with Loch Ness and Loch Lochy.

OILS. Under this head is ranged a group of organic compounds of great interest, both on account of their great economic value, and from the fact that they occur abundantly both in animals and plants. They consist chiefly of carbon and hydrogen, but more or less of oxygen is generally associated with them, and causes considerable

variation in their qualities. They are either solid or liquid, and in the former condition are more frequently termed *fats*. These fats are more abundant in the animal than in the vegetable kingdom. Oils, whether liquid or solid, usually consist of three other substances, two of which, *stearine* (*στέαρ*, suet), and *margarine* (*μάργαρον*, a pearl), are solid; and the other, *elaine* or *oleine*, is liquid at ordinary temperatures. They are all from 6° to 9° lighter than water, and their liquid or solid condition depends upon the proportion in which their component parts are mixed. Thus, in the fats the oleine exists in small quantity, and in the liquid oils it is the chief constituent. A certain degree of heat is necessary to the mixture, for at low temperatures there is a tendency to separation: the stearine and margarine are precipitated and solidified, and, if pressed, can be entirely freed from the oleine. Both oils and fats, when boiled with water and alkali, undergo the peculiar process of *saponification*, or, in other words, solidify, and become converted into soap; during this process a liquid of a sweet taste, called glycerine, is given off. (See **GLYCERINE**). Glycerine exists in oil and fats as a base to which stearic, margarinic, and oleic acids are united, forming stearine, margarine, and oleine.

The principal uses to which oils and fats are applied are soap-making, illumination by candles or oil, lubricating machinery, and dressing cloth. They are easily separated by moderate pressure from the animal or vegetable tissues which contain them, but are not usually pure until they are rendered so by clarifying.

Of the animal oils, those are chiefly solid which are yielded by the mammals and birds; whilst those derived from reptiles and fishes are for the most part liquid at the ordinary temperature. The true oils and fats are unchanged when heated even to a temperature above 400°; but there is another group of compound substances, termed *essential oils*, yielded by the vegetable kingdom, which are volatile at ordinary temperatures; hence the term *fixed oils* is often applied to the former, and *volatile oils* to the latter. The volatility of the essential oils renders distillation a ready means of procuring many of them. They resemble the fixed oils in many respects, but differ materially in others; for instance, they do not undergo saponification when treated with alkalies; like them, however, they often separate at low temperatures into solid and liquid portions,—the former called *stearopten*, the latter *elaopten*. They are very slightly soluble in water, and they differ materially in the sensation they produce on the skin. Instead of the smooth soft feel of the true oils, they are harsh and rough to the touch. The essential oils are mostly pure hydro-carbons, but many are capable of absorbing oxygen when exposed to the air, which darkens their colour, and renders them resinous in appearance, a result which may be seen generally around the mouths of bottles in which they are kept. Some are obtained already oxidized, and some are found to contain sulphur: hence they have been classified as *pure hydro-carbons*, when free from oxygen; *oxidized essences*, when obtained in combination with oxygen; and *sulphuretted essences*, when combined with sulphur. The combinations which the essential oils enter into render them peculiarly interesting to the student in organic chemistry. They appear to be the cause of all the more remarkable odours and flavours which characterize plants; and as they can generally be separated easily, they are very valuable in an economic point of view, affording us the means of concentrating and retaining the perfumes of the most evanescent flowers, and in the same way of preserving the most pungent and delicate flavours.

Essential oils are in some instances procured by simple pressure, as those from the rind of the orange tribe; others are distilled with water, and float upon the condensed water in the receiver. Some, however, are so easily destroyed by these processes, that they can only be obtained by the power

Oils.

Oils.

which the fixed oils have of absorbing them. Thus, essence of jessamine is obtained by placing layers of the freshly-gathered flowers between layers of cotton-wool saturated with the fixed oil of almonds or of poppy seed, both of which are themselves odourless. They, however, soon absorb the essential oil naturally emitted from the flowers, and become highly perfumed. Fresh layers of flowers are supplied until the fixed oil is saturated, when it is pressed out from the cotton-wool.

Rock oil.

Besides the fixed oils and fats, and the essential oils, there is a mineral product called rock oil; it is not, however, properly speaking, an oil, but is a variety of petroleum, which exists abundantly in some bituminous shales. Works have been established in Dorsetshire and other parts of the kingdom for obtaining this material, but without much success. Large quantities are, however, brought from Rangoon, in the Burmese empire, chiefly to Liverpool, where nearly 700 tons weight were imported in 1857. Works exist at St Helen's, near Liverpool, and other places, where from this material, which is of a dark greenish-brown colour, and nearly the consistency of butter, a light amber-coloured oil-like liquid is obtained, said to be very useful as a lubricant for machinery. A considerable proportion of paraffine is obtained from it, and it yields a very volatile naphtha.

Sources of oils.

In enumerating the oils, those produced from the animal kingdom will be first mentioned, and in the order of zoological classification; then the fixed vegetable oils; and finally the three classes of essential oils. Of the twelve orders into which naturalists divide the mammalia, only four comprise animals which yield oils of economic value. These orders are Carnivora, Cetacea, Ruminantia, and Pachydermata.

Animal oils.

Of the carnivorous animals yielding oleaginous products, we have first the bear. The black bear (*Ursus Americanus*, Gmelin), a native of North America, yields an abundance of grease or soft fat; which is collected by the hunters who pursue the animal for its skin and hams, and is occasionally imported into this country, not, as some may suppose, to be used by the hair-dressers and perfumers for pomades, but for the more useful manufacture of candles, &c. But the principal oil-producing carnivora are the seals, several species of which are killed on purpose. The quantity of seal oil imported is very great. Most of it comes from Newfoundland. The species which chiefly yield it are *Callocephalus Grænlændicus*, *Callocephalus vitulinus*, *Phoca barbata*, and *Arctocephalus Falklandicus*. The part which yields the oil in these animals is the blubber, a peculiar layer of oil-cells which lies immediately under the skin of the animal, and in fact constitutes a portion of the skin itself. Seal oil is liquid, and, when pure, of a pale straw-colour. The first drawings from the blubber give the purest oil, which is obtained without pressure; but the succeeding drawings from the blubber-cask are more or less deeply coloured brown by the decomposition of the oil-cells.

The Cetacea are remarkable for the extent of this peculiar skin-development called blubber, which in some species is one or two feet in thickness. This is not, however, the only source of the whale oil; for in the great-headed cachalot or sperm-ceti whale (*Catodon macrocephalus*, Cuv.), the gigantic head, which nearly equals the body in bulk, has an enormous receptacle on the upper part of the skull, from which oil is obtained. This receptacle consists of a dense bag, divided into numerous large cells or compartments, in which the oil exists in a semi-fluid state, owing to the large quantity of stearine or spermaceti which it contains, and which can easily be separated from it by simple draining or slight pressure. The quantity of oil yielded by some of the larger whales, especially the cachalots, is enormous, but is often erroneously stated, owing to a misunderstanding of the fact that quantity in liquid oils is calculated by the *ton* measure, and not by the *ton* weight, as with solid oils or fats. A cachalot commonly yields 20 tons, or 5040 gallons; and single whales have been known to yield 30 tons (7560 gallons). The following oils derived from the whale tribe are known in commerce:—*Sperm Oil*, and its stearine, *Spermaceti*, from the cachalot; *Train* or *Common Whale Oil*, from the Right Whale (*Balaena mysticetus*) and other species;

Oils.

Pot-head Oil, from both *Globicephalus deductor* and *Globicephalus Suineval*; and *Porpoise Oil*, from *Phocæna communis*. These oils are usually imported as train or sperm oils; but the brokers are well skilled in distinguishing them.

Of the ruminating animals, we have only two species which yield oleaginous products; but they are unequalled in value by any others. They are the ox (*Bos taurus*, Linn.), and the sheep (*Ovis ammon*, Linn.) The fat of both these animals melted down constitutes the tallow of commerce. They are so generally mixed together that there is no possibility of ascertaining the exact amount yielded by each. We receive our largest supply from Russia; but we import considerable quantities from Denmark, Prussia, the Hanse Towns, Holland, Turkey, South America (particularly Buenos Ayres and Monte Video), the Cape of Good Hope, the East Indies, Australia, &c. That imported from the ports of Monte Video and Buenos Ayres is chiefly, if not altogether, ox tallow; whilst that from Australia is principally from the sheep. Besides the enormous quantity imported, we have to take into consideration that which is produced in Great Britain, which has been computed to be equal to the amount imported.

From the bones of the feet of oxen a valuable oil is obtained. It contains comparatively little of the harder portion (stearine), and is in a fit state to be used for machinery. It is procured by boiling the bones, and skimming off the fatty oil as it rises to the surface of the water. It is called neats-foot oil; and from the fact that it remains liquid at a temperature below 32°, and is not liable to rancidity, it is peculiarly well adapted for turret clocks and other machinery much exposed to cold. The supply from such a source is necessarily limited.

Of the Pachydermata only two yield oily products of any commercial importance. The first of these in point of value is the common hog (*Sus scrofa*, Linn.), the fat of which, under the name of *lard*, is very extensively used. Considerable quantities are consumed in articles of food. Most of the ointments of the pharmacist have lard for their base; and when too rancid for these purposes, it is used for greasing machinery, especially the axles of railway carriages. In the United States the production of lard is immense; and its stearine, which is easily separable from the elain, is extensively used in the manufacture of candles. The liquid stearine, under the name of lard oil, is used for the finer parts of machinery, and for that purpose is extensively imported into this country from Europe and America. The fat of the horse does not, when melted, possess the same firm consistency as that of the ox, sheep, and swine. The proportion of stearine in it being comparatively small, it is only within the last eight years that it has attracted any attention; but now it constitutes an important article of trade with Buenos Ayres and Monte Video, whence it is imported under the names of horse or mare's grease. The latter name is, however, more generally applied. From its liquidity, it is extremely penetrating; hence the ordinary packages for grease and tallow were found to be insufficient, as the casks were frequently half empty on their arrival. This checked its introduction for some time; but it is now put into square boxes lined with tin, and arrives without loss. It is found to answer very well as a lubricant for machinery.

From the classes comprising the birds and the reptiles (Aves and Reptilia) neither oils nor fats of any importance are obtained, although the domesticated birds sometimes produce it in abundance. That of the goose, under the name of goose-grease, is occasionally heard of as a useful domestic remedy for various ailments.

The class of fishes (Pisces) is a considerable source of oil, always of a clear liquid quality. It is nearly all yielded by one species, the common cod-fish (*Gadus Morrhua*, Linn.). The *Cod Oil*, and the *Cod-liver Oil* of commerce, are both obtained from the liver of the fish; the latter, which is now so extensively used medicinally, being only prepared with a little more care. Its principal value as a remedial agent appears to depend upon its nutritive qualities, and the digestive powers of a portion of *pepsin*, or biliary matter, which is always present, and which may be detected by the application of a drop of concentrated sulphuric acid, when, if the oil be really cod-liver oil, a beautiful purple colour will be immediately produced. The number of cod-fish captured is incalculable. The cod-fishers, in opening the fishes to salt and dry them, carefully preserve the livers, for which an extra boat is usually in at-

Oils.

tendance; these are taken on shore, and piled up in immense masses exposed to the sun. The heat soon makes the oil run from the livers in considerable abundance, and for a short time it is very clear, and of a light straw colour,—this is the first quality, and is kept by itself. As the livers begin to decompose, however, they give a darker colour to the oil, and several qualities are obtained, the last of which is thick, turbid, and extremely offensive to the smell, and is known under the name of cod-pitchings. A small quantity of oil made from the common herring (*Olupea harengus*, Linn.) is imported from time to time from North America; but its strong and unpleasant odour prevents it from being much used.

Vegetable oils.

The vegetable sources of oils are very numerous, and some are of great importance.

FIXED VEGETABLE OILS.—Of these the most important is *Olive Oil*, procured from the ripe fruit of the olive (*Olea Europæa*, Linn.), which is cultivated for this purpose through all the countries of Southern Europe and Northern Africa. Its native country is Asia. On Lebanon and the Mount of Olives, and in the neighbourhood of Aleppo, the olive tree still grows wild. Its general diffusion through the countries suitable to its growth is no doubt attributable to the Romans, although the Carthaginians and others had previously procured and cultivated it. Pliny says (book xv., Bohn's edition), "Fenestella tells us that in the year of Rome 173, being the reign of Tarquinius Priscus, it did not exist in Italy, Spain, or Africa; whereas at the present day it has crossed the Alps even, and has been introduced into the provinces of Gaul and the middle of Spain. In the year of Rome 505, Appius Claudius, grandson of Appius Claudius Cæcus, and L. Junius, being consuls, 12 pounds of oil sold for an *as*; and at a later period, in the year 680, M. Seius, son of Lucius the curule ædile, regulated the price of oil at Rome, at the rate of 10 pounds for the *as*, for the whole year. A person will be the less surprised at this, when he learns that twenty-two years after, in the third consulship of Cn. Pompeius, Italy was able to export oil to the provinces." Its value has never decreased; and, next to corn, olive oil is still perhaps the greatest necessity of the nations of Southern Europe. It has been described as the cream and butter of Spain and Italy; and the quantity consumed in those countries as food, entering into their cookery in every imaginable way, is immense. There are several varieties in cultivation, which vary much in quality. That which yields the sweet Italian and French salad oils is the var. *β. longifolia*, Aiton. Its fruit, when pickled unripe, is also most highly prized. The inferior oils of Spain are made from the large olive, var. *δ. latifolia*, Aiton. In Italy and France the oil is obtained by crushing the fruit in mills,—the grinding stones of which are so set that they will thoroughly crush the pulpy part of the fruit without breaking the stone or kernel in the centre. The fruit, which is gathered for the purpose when very ripe, is not unlike a small damson in shape and colour, and the stone in the centre is very hard. After crushing in the mill, the pulp is put in bags made of rushes and slightly pressed, when the fine or virgin oil flows out abundantly. Afterwards the cake or *marc* is again broken up, mixed with water, and returned to the press, and an oil of an inferior quality is obtained. The cake or *marc* is once more broken up and mixed with water, after which it is placed in vats to ferment, and then again pressed. The result is an oil of a very inferior sort, only useful to the soap-makers. The oil of the olive is liquid at the ordinary temperature, but becomes solid a few degrees below 32°. In Spain the process is less carefully conducted. Instead of being gathered by hand, the olives are beaten from the trees, and are consequently much mixed—ripe, unripe, and decayed. They are left in large heaps on the ground to ferment, which partly breaks up the oil cells; they are then ground and pressed, and yield a very inferior oil. The finest virgin oil for table use is imported from Leghorn and from France. The common oil is chiefly used in England for dressing woollen cloths, for which purpose vast quantities are required in Yorkshire, the west of England, and other cloth districts. On the Continent it is also employed in making soap. In 1856 the imports were as follows:—From France, 358 tuns; Portugal, 3175 tuns; Spain, 2,301 tuns; Sardinia, 907 tuns; Tuscany, 1,973 tuns; Two Sicilies, 6,093 tuns; Turkey, 491 tuns; Morocco, 2579 tuns; Malta, 360 tuns; Ionian Islands, 2900 tuns; other parts, 278 tuns; in all, 21,415 tuns, or 5,395,580 gallons, valued at L.1,124,755.

Palm Oil is obtained from the fruit of the oil palm (*Elæis Guineensis*, Linn.), a native of Western Africa, by crushing the thin fleshy covering which surrounds the hard stone or seed, and by pouring boiling water upon the pulp, upon which the oil floats and is skimmed off. In this process, however, much of the colouring matter of the drupe, which is a fine orange-yellow, is retained, which, besides its colour, imparts to the oil a sweet violet-odour. Palm oil, when imported, is of the consistence of butter. Vessels arrive entirely laden with it. It is put in casks of various sizes, but usually very large, and made to suit the stowage of the vessels. Spirits, tobacco, cutlery, cloths, beads, cowries, arms, gunpowder, and other articles, are given in barter to the natives in exchange for the oil. This trade has now obtained an immense importance, owing to the valuable discoveries by which the oil can be deprived of its colour, and a solid part, called palmitic acid, converted into candles of a very superior quality. The addition of sulphuric acid entirely carbonizes the yellow vegetable colouring matter. It is then submitted to the action of steam, at a temperature of 612°, in a still of peculiar construction, which carries over the particles of oil with the steam, leaving behind the charcoal or carbonized vegetable matter. Previous to the distillation, however, lime is added to neutralize the acid, and that also remains behind. The material which comes over runs from the still as a clear colourless oil, which upon cooling has the colour and consistency of lard in cold weather. This is cast into square cakes about $1\frac{1}{2}$ inch in thickness, and 18 inches square. The cakes are placed between mats made of coir, or cocoa-nut fibre, and submitted to the action of powerful hydraulic presses, which force out the *elain*, a liquid about the colour and consistency of linseed oil. The mats are then taken from the press, and the cakes, which are now much harder, are remelted and made into candles. Nothing can give a better idea of the extent to which this manufacture is carried on than the fact, that Messrs Price and Co., at their works in London, and at Bromboro' Pool, Cheshire, are now making 150 tons of these candles per week, and give employment to upwards of 2000 persons. Great quantities are also consumed in the manufacture of soap. When it is remembered that each drupe will only yield about $\frac{1}{16}$ th part of an ounce in weight, and that each palm only produces three or four pounds at one crop, the number of palms in the forests of Western Africa must be immense, and the industry called into action by this want of civilized man must exert a most beneficial influence over the destinies of the African races. The drupes are borne in immense clusters, each surrounded by sharp bracts, and they greatly resemble gigantic pine-apples both in shape and colour.

Cocoa-nut Oil is produced from the white kernel which lines the shell of the large cocoa-nut (*Cocos nucifera*, Linn., Nat. Ord. *Palmaceæ*). This kernel is ground in mills in Ceylon, where it is largely cultivated for its oil; and when ground, the mass, called *copperah*, is submitted to considerable pressure. The oil runs at first limpid and liquid, but it afterwards becomes white and solid. It is largely used in making soap, and also in making candles; for the latter purpose the *stearine* only is used. The *oleine*, both of cocoa oil and palm oil, is used for lubricating machinery. It is nearly all obtained from Ceylon, whence it is exported chiefly to this country in large casks and iron tanks.

Linseed Oil is pressed from the seed of the flax plant (*Linum usitatissimum*, Linn., Nat. Ord. *Linaceæ*). It is not imported very largely, being chiefly manufactured in this country from home-grown or imported seed. The seed is first ground in mills, and afterwards submitted to enormous hydraulic pressure. The oil yielded is of a dark brown colour, and is one of the best drying oils. It is therefore of great value to painters, who use this oil almost exclusively in mixing their paints. Linseed is imported in very large quantities from the East Indies, Russia, Germany, Holland, America, and other places. The total quantity received in 1856 was 1,180,180 quarters, valued at L.3,195,634. This does not represent the value of the oil, for the cake or *marc*, which remains after the oil is expressed, is of considerable value for feeding cattle.

Seed Oil is a name applied to the expressed oil of the physic-nut (*Jatropha curcas*, Linn., Nat. Ord. *Euphorbiaceæ*). Within the last six years this oil has been brought into notice as a substitute for the dearer olive oil in dressing woollen fabrics. It has highly purgative properties; and the seeds imported, under the name of croton nuts, produced serious results

Oils.

Oils.

when first landed on the Liverpool quays; the tempting name induced many to eat their blandly flavoured white kernels, and the consequences were nearly fatal to some. The oil, too, at first produced disagreeable effects amongst the workmen, who have a habit of tasting with their fingers the various oils they use. This evil, however, soon cured itself, and the oil is now largely used. It is chiefly imported into Liverpool from Lisbon, but the Portuguese manufacturers obtain the seeds from the Cape de Verde Islands. There is no doubt that vast quantities might be obtained from the West Indies, where the plant is indigenous. It is cultivated in the East Indies, and its oil is called *Bhoga Bhirindi til*. The imports have reached nearly 400 tons per annum; but owing to the indefinite name given to it, this oil is confounded with others, and the exact quantity cannot be ascertained. The importers also have some interest in suppressing information respecting its source and true character. It is a good drying oil, and would probably, if boiled, be equal to linseed oil for painters' purposes.

Sessamum or *Gingely Oil* is made from the seed of *Sessamum orientale*, Linn. (Nat. Ord. *Pedaliaceæ*). This seed is grown extensively all through India, where its oil is known under various names, as *Tillee Oil*, *Manchy noonæ*, *Til ke tel*, *nullenai*, *tamool*, &c. The seed is small, not much unlike the flax seed in shape: the colour usually a light drab—but there are dark-coloured varieties. The oil is bland and sweet, and useful for all purposes to which the common kinds of olive oil can be applied. In 1856, 5269 quarters of this seed were imported for expressing the oil; and of the oil itself in 1857, 42,136 gallons, or nearly 166 tons. The *marc* or oil-cake is much relished by cattle, and is very nutritious.

Niger-seed Oil is expressed from the seeds of *Verbesina sativa*, H. K., or *Guizotia oleifera*, Cassini (Nat. Ord. *Compositæ*), another East Indian seed, also extensively used in that country under the names of *Ram til*, *Valisaloo Oil*, *Valisaloo noonæ*, &c. The seed only is imported here. It is black and shining, resembling in shape the common sunflower seed, but is scarcely larger than a caraway seed. The oil is as sweet and liquid as that of the olive, and answers the same purposes. About 700 quarters were imported in 1857.

Safflower-seed Oil is expressed from the seeds of the safflower plant (*Carthamus tinctorius*, Nat. Ord. *Compositæ*), also a native of India, where it is very extensively cultivated, both for its flowers and seed. The latter are of the same shape and size as those of the sunflower, but are white instead of black. They yield a large quantity of a fine clear oil, of a peculiar golden-yellow colour. It has good drying properties, and burns well, but has a peculiar and not very agreeable odour. There is good reason for believing that this oil, known in India under the name of *Koosum Oil*, is the celebrated Macassar oil of the Malays, and, in all probability, of our own perfumers. It has certainly a specific effect upon the growth of the hair. The oil is not often imported, but a large quantity of the seed now finds its way annually to this country; but as the official designation of "seed unenumerated" is applied to this and many others in the returns, the exact quantity cannot be ascertained. Between 300 and 400 quarters were imported in 1857 into the port of Liverpool, and probably a much larger quantity into London.

Rape Oil is expressed from the seeds of *Brassica rapa*, and its variety *B. oleifera*, De Cand. (Nat. Ord. *Cruciferae*), a common European weed, which is, however, largely cultivated for its seed. It yields a yellowish-brown oil in considerable abundance, valuable for burning and other purposes. Several other *cruciferous* plants, yielding a similar oil, are also largely imported under the same name, and are consequently confounded with it. Thus we have immense quantities of the seed of *Sinapis toria*, *S. glauca*, *S. nigra*, sent from India under the name of rape-seed, and the colza or colza seed (*Brassica campestris*, var. *α oleifera*, De Cand.) is imported from Holland and Germany, and finds its way into our markets under the same designation. The quantity of seed imported as rape in 1856 was as follows:—From Russia, 2556 qrs.; Denmark, 4402 qrs.; Germany, 2267 qrs.; Holland, 1850 qrs.; British East Indies, 251,890 qrs.; other parts, 1955 qrs.;—or 264,920 quarters in all, in which probably not more than 8000 quarters are genuine rape-seed. Besides the seed, a considerable quantity of the oil was imported from the continent of Europe.

Ground-nut Oil is yielded by the seeds of *Arachis hypo-*

Oils.

gæa, Linn. (Nat. Ord. *Leguminosæ*). The seeds are about the size of a small horse-bean, generally two in a pod. They are much used, when roasted, as food both in South America (its native country), and also in Africa, India, and China, in which countries it is now naturalized and grown to a great extent. The oil is thin and limpid, burns well, and is a good substitute for olive oil, both for the table and other purposes, as it is remarkably free from rancidity. It is almost pure elain, and has accordingly been recommended for watch and clock-work, and other delicate machinery. The quantity of the seeds imported in 1857 was about 2500 tons. Some small lots of the oil have also been imported, but the exact quantity cannot be ascertained. It is known in India under the name of *Katchung Oil*.

Castor Oil is expressed either with or without heat from the seeds of the palma-christi plant (*Ricinus communis*, Linn., Nat. Ord. *Euphorbiaceæ*), a native of the East Indies, where it is known under many names. In Tanjore the native name of that which is obtained by putting the crushed seeds into hot water is *Adivia aumedum*. It is used for burning in lamps. That which is expressed without heat, and is consequently known here as *cold-drawn*, is there called *Arandee ka tel*. Only the cold-drawn is sent to this country, and it is nearly all used for medicinal purposes, in consequence of its valuable aperient qualities. It is now disseminated pretty generally through all tropical and subtropical countries. About 1200 quarters of the seed were imported in 1857, besides large quantities of the oil. Another seed is imported for the purgative oil which it yields, but the quantity is very small. It is the fruit of *Croton Tiglium*, Lam. (Nat. Ord. *Euphorbiaceæ*), also a native of India; the oil is never used except for medicinal purposes. The seeds of *Jatropha curcas*, before-mentioned, are often imported as croton seeds, but not more than a few bushels of the real croton seeds are annually brought to this country.

Poppy-seed Oil, obtained from the seed of the white poppy (*Papaver somniferum*, Linn., Nat. Ord. *Papaveraceæ*), is most likely of Asiatic origin. It is cultivated chiefly for its narcotic juice (opium), but the value of its seed for oil purposes is rapidly increasing; and the fact that it is easily cultivated in France and other temperate parts of Europe, adds much to its interest. Thousands of acres of land in France alone are now annually covered with crops of the white poppy, grown only for its seed, which yields a sweet limpid oil, esteemed by many as preferable for most purposes to that of the olive, especially as a salad oil. The impression which long prevailed, that the seed of a plant producing so poisonous a juice as that of the poppy could not be otherwise than injurious, actually led to legislative enactments against its introduction into France in former times. But, like those in our own country against logwood, they have long since passed away, and poppy oil and logwood are now amongst the most useful of our commercial materials. In 1856, 24,121 qrs. of this seed were imported, of which no less than 24,073 qrs. were from British India. The oil has not been imported, unless in very small quantities, from France.

Almond Oil is expressed from the kernel of the common almond (*Amygdalus communis*, Linn.) The value of the sweet varieties for other purposes causes the small bitter almond to be generally used for expressing this oil, especially as the essential oil can afterwards be distilled from the *marc*. The fixed oil of almonds is chiefly manufactured in France; it is much used by perfumers, as it is very nearly inodorous, and will consequently receive the most delicate perfumes. It is an expensive oil, as it requires 1 cwt. of almonds to obtain 50 lbs. of oil. It is of a light yellow colour, and contains very little stearine, only about 24 per cent. It is often adulterated with the oil of *Guizotia oleifera*. Besides its chief use by the perfumers, it is also, to a small extent, used in the operations of pharmacy. The imports are small, and published returns contain both the fixed and volatile oils, consequently the exact quantity of each cannot be ascertained. Most of that used in Great Britain is home manufactured.

Amongst the less known oils and vegetable fats are the *Madia Oil*, yielded by the seed of *Madia sativa*, Molina (Nat. Ord. *Compositæ*), a native of Chili, and cultivated in Italy for the sake of its oil, which is limpid and sweet. *Gold of Pleasure Oil*, from the seed of *Camelina sativa*, Cranby (Nat. Ord. *Cruciferae*), a native of the continent of Europe. It does not succeed well in England, but the oil is used for many purposes

Oils.

on the Continent, being even employed in culinary preparations. *Oil of Mexican poppy-seed* (*Argemone Mexicana*, Linn., Nat. Ord. *Papaveraceæ*) is a drying oil, and is used in Mexico, its native country, for polishing wood. It is also employed for various useful purposes in the East and West Indies, where it is now cultivated. *Indian Almond Oil*, a sweet limpid oil, is obtained from the kernels of *Terminalia catappa*, Linn. (Nat. Ord. *Combretaceæ*). This tree is a native of India, and is now cultivated in the West Indies. The kernel is not very large, but closely resembles the almond in flavour. The oil has not yet been imported. *Walnut Oil*, expressed from the kernel of the common walnut (*Juglans regia*, Linn., Nat. Ord. *Juglandaceæ*), is extensively manufactured in Circassia, where the tree is very abundant. It is used by the natives for almost every purpose to which oil is applied, but it is not exported.

The following liquid oils were exhibited in the Indian collection at the Exhibition of 1851, but no information given as to their uses or commercial value. *Cheeronjee Oil*, from the seeds of *Buchanania latifolia*, Roxb. (Nat. Ord. *Anacardiaceæ*). *Valuse nune*, from the seeds of *Guizotia abyssinica* (Nat. Ord. *Compositæ*). *Poonseed Oil*, expressed from the nuts of an unknown species of *Calophyllum* (Nat. Ord. *Clusiaceæ*). *Oondee Oil*, from the nuts of *Calophyllum inophyllum*. *Caju-apple Oil*, from the cashew-nut, *Anacardium occidentale*, Linn. (Nat. Ord. *Anacardiaceæ*). *Neem Oil*, obtained from the pulp of the margosa-berries, or fruit of *Melia azadirachta*, Linn. (Nat. Ord. *Meliaceæ*). *Kurrunj Oil*, expressed from the nut of *Pongamia glabra*, Ventenat (Nat. Ord. *Leguminosæ*). Its chief value is in veterinary medicine. *Country Walnut Oil*, from the kernels of *Aleurites triloba*, Forst. (Nat. Ord. *Euphorbiaceæ*). *Country Walnut Oil*, from the seeds of *Bergera Königii*, Roxb. (Nat. Ord. *Aurantiaceæ*). *Hingun or Hingota Oil*, from the seeds of *Balanites Ægyptiaca*, Delile (Nat. Ord. *Amyridaceæ*). *Oil of Ben*, from the seeds of *Moringa pterygosperma*, D. C. (Nat. Ord. *Moringaceæ*). *Mooneela Grain Oil*, from the grain of *Dolichos biflorus*, Linn. (Nat. Ord. *Leguminosæ*).

SOLID OILS, OR VEGETABLE TALLOW.—*Kokum or Cokum Oil*, made from the fruit of *Garcinia purpurea* (Nat. Ord. *Clusiaceæ*), is now frequently imported from India, usually in large candle-shaped rolls about eighteen inches in length, and from one to three inches in diameter. This oil has a sweet balsamic smell, and is said to be wholly used by the candle-makers for their best kind of candles.

Muohwa Oil, or *Bassia Butter*, is made from the large seeds of *Bassia latifolia* and *Bassia longifolia* (Nat. Ord. *Sapotaceæ*). This material, which is rather softer than butter, and of a yellow colour, is used in India for food, burning in lamps, and making soap. It was first imported into England during 1857. The quantity, however, was very small.

Chinese Vegetable Tallow, obtained from the seeds of *Stillingia sebifera* (Nat. Ord. *Euphorbiaceæ*), by placing them in boiling water, is white, and harder than common tallow. In China it is used for making candles, and in this country it has been employed to give firmness to softer fats, but the quantity sent is very small and uncertain.

ESSENTIAL OILS OR ESSENCES.—These are all of vegetable origin, usually of a pale yellow colour; lighter than water, and nearly all liquid at the ordinary temperature. They appear to constitute the odorous and sapid principles of plants. They are slightly soluble in water, perfectly so in alcohol or ether; and they evaporate so readily that their adulteration by any of the fixed oils may be readily detected by a drop of the oil being applied to white paper. The greasy spot will entirely disappear if held before the fire, provided the essential oil be unmixed; but if a fixed oil has been added, the greasy stain will remain. They are obtained chiefly by distillation from various parts of plants, as the wood, bark, leaves, flowers, fruits, and seeds. Some, however, are obtained by expression and other means. The essential oils or essences, as they are frequently called, are arranged by chemists under the three following divisions:—

1st. *Pure Hydrocarbons*, the principal of which are:—*Oil of Turpentine*, yielded by several trees of the Nat. Ord. *Coniferae*, the principal of which are *Pinus tæda*, Linn., *Pinus palustris*, H. K., and *Abies excelsa*, Poir. It is obtained by making holes in the base of the stem, from which a very large quantity of the fluid substance called turpentine flows and is

collected in casks. This is of a light yellow colour, and of the consistency of thin honey; but soon gets hard, by the evaporation of its essential oil. Turpentine, when distilled, yields about 25 per cent. of a thin, colourless essential oil, known as spirit or oil of turpentine, which is chiefly manufactured in this country from turpentine imported from the United States; but a considerable quantity is also sent from America. *Oil of Orange Peel*, from the yellow part (*flavedo*) of the rind, is imported from Sicily, and is used in perfumery. *Oil of Orange Flowers*, or *Oil of Neroli*, from the petals of the flowers, is used in perfumery, and is imported from Italy. *Oil of Orange Leaves*, or *Oil of Petit-grain*, from the leaves and the immature fruit which falls off soon after the flowers, is used in perfumery. It is imported from Italy and France. *Oil of Lemon*, from the yellow portion (*flavedo*) of the peel of the fruit, is used largely in perfumery; and imported principally from Sicily. *Oil of Bergamotte*, from the rind (*flavedo*) of the Bergamotte orange, is used in perfumery, and is imported from Sicily. *Oil of Cloves*, from the spice called cloves, is used in confectionary and perfumery; and is chiefly distilled in England. *Oil of Pimento*, from the spice called Jamaica pepper, allspice, or pimento, is used in perfumery and confectionary; it is chiefly made in England. *Oil of Caraway*, from caraway seeds (the fruit of *Carum Carui*, L., Nat. Ord. *Umbelliferae*), is distilled chiefly in this country for perfumery and confectionary. *Oil of Camomile*, from the dried flowers of the camomile (*Anthemis nobilis*, L., Nat. Ord. *Compositæ*), is prepared in England; it is used only in medicine. *Oil of Juniper*, from the berries of *Juniperus communis*, L., (Nat. Ord. *Coniferae*), usually imported from Holland, is used principally in veterinary medicine. *Oil of Thyme*, from the whole plant of *Origanum vulgare*, L. (Nat. Ord. *Labiatae*), is used in veterinary medicine; and is both made in England and imported from the continental ports. *Oil of Peppermint*, from the whole plant of *Mentha piperita*, L. (Nat. Ord. *Labiatae*), is used chiefly in confectionary. It is imported in considerable quantities from the United States and from the European ports; but the best is that manufactured in England, at Mitcham, in Surrey, where the cultivation of plants yielding essential oils is extensively carried on; and the distillation of the oils carried to so high a degree of perfection, that the prices realized are often nearly double that of the foreign ones. *Attar*, or *Oil of Roses*, is procured from the leaves of the rose (*Rosa centifolia*, L., Nat. Ord. *Rosaceæ*). This most delicate perfume is only made in India and Persia. The chief manufacture is at Ghazipore, on the Ganges, where thousands of acres of roses are cultivated. The petals of the flower are distilled with water, which comes over highly perfumed. This water is then set aside in basins, carefully covered over to prevent impurities being blown in; and each morning the film of oil which has risen to the surface during the cool hours of night is carefully skimmed off with a feather, and placed in small glass bottles. When pure, it is extremely valuable; the present price in this country being about 80s. per ounce. It is too generally adulterated either with the odourless fixed oil of almonds or gingly, or the sweet-scented oil of *Andropogon calamus-aromaticus*, a grass which yields an abundance of rose-scented essential oil. Sometimes it consists almost entirely of this sophistication; but it is coarse and disagreeable to the practised perfumer, and can easily be detected; besides which, it remains liquid at the ordinary temperature, whereas pure otto of roses is solid at 83°F. The Persian is chiefly received from Turkey, and is generally considered the best. *Oil of Birch* is distilled in Russia from the bark of the common birch (*Betula alba*, L., Nat. Ord. *Betulaceæ*). It has a sweet cedar-like odour, and is used in dressing Russia leather, to which it communicates its peculiar smell. Lately small quantities have been imported for preparing leather in a similar manner.

2d. *Oxidized Essential Oils.*—*Oil of Mint*, distilled from the whole plant of common mint (*Mentha sativa*, L., Nat. Ord. *Labiatae*), is chiefly made in England; and used only in pharmacy. *Oil of Penny Royal*, distilled from the whole plant of *Mentha Pulegium*, L. (Nat. Ord. *Labiatae*), is made in England for medicinal purposes. *Oil of Cassia*, distilled from the bark of *Cinnamomum Cassia*, Blume (Nat. Ord. *Lauraceæ*), is manufactured in China, and imported in considerable quantities, usually in chests like those used for tea, each containing four tin canisters filled with the oil. It is used in perfumery. *Oil of Cinnamon*, distilled from cinnamon or

Oils.

the bark of *Cinnamomum zeylanicum*, Nees (Nat. Ord. *Lauraceæ*), possesses, when pure, all the delicious flavour and pungency of the spice, and is used for similar purposes. Small quantities only are imported from Ceylon. It is frequently adulterated with oil of cassia. The essential *Oil of Almonds* is usually distilled from bitter almonds, although it can also be obtained from the sweet varieties quite as easily; but for economy the cake of the former, from which the *fixed* oil has been expressed, is chosen. When first distilled, this oil contains hydrocyanic or prussic acid, and is consequently a dangerous poison; but when purified by mixing with lime, and the proto-chloride of iron, and re-distilling, it becomes quite innocuous. *Oil of Lavender*, distilled from the flowers of *Lavandula vera*, De Cand. (Nat. Ord. *Labiatae*), is only used in perfumery. The best is made at Mitcham; but considerable quantities are imported from France and Italy. An inferior kind is made from the flowers of *L. spica*, and is known in commerce as oil of spike. *Oil of Rosemary*, distilled from the leaves and flowers of *Rosmarinus officinalis*, L. (Nat. Ord. *Labiatae*). It resembles oil of lavender, and is chiefly

made in England and France. *Oil of Aniseed*, is distilled both from the seeds of *Pimpinella Anisum*, L. (Nat. Ord. *Umbelliferae*); and from those of *Illicium anisatum*, L. (Nat. Ord. *Magnoliaceæ*). It is imported in the same manner as oil of cassia, in considerable quantities from China; and is used in medicine, perfumery, and the manufacture of liqueurs. The oils distilled from different species of the genus *Andropogon* (Nat. Ord. *Graminaceæ*) are imported from Ceylon, and used in perfumery. *Oil of Citronelle*, from *A. citratum*, De Cand., has a lemon odour. *Oil of Verbena*, from *A. Schœnanthus*, Linn., resembles the perfumed verberna (*Aloysia citriodora*). *Oil of Rose-scented Geranium* (from *A. Calamus-aromaticus*, Royle) is also produced abundantly in India, where the native medical practitioners use it as a rubefacient for rheumatism. It is also used in perfumery, and particularly to adulterate the otto of roses.

3d. *Essential Oils containing Sulphur*.—This division embraces only a few chemical oils, such as oils of mustard, garlic, horse-radish, and some others of no general importance.

Oise.

Imports and Exports of Oils in 1857, with the Current Prices and estimated Value (compiled from the Brokers' Circulars).

(T. C. A.)

OISE, a department of France, lying between N. Lat. 49. 4. and 49. 46.; E. Long. 1. 42. and 3. 8.; is bounded on the N. by Somme, E. by Aisne, S. by Seine-et-Marne and Seine-et-Oise, and W. by Eure and Seine Inférieure. Its form is nearly that of a parallelogram; its length from E. to W. is 65 miles, average breadth about 40 miles; area 2244 square miles. The surface is undulating, with a general slope to the S.W., except a narrow strip of land in the N. of the department, which slopes towards the N. A chain of hills traverses it near its northern boundary, and another runs parallel to the left bank of the Oise; but none of the elevations exceed 850 feet above the level of the sea. The principal river is the Oise, from which the department takes its name. It rises near Chimay, in the province of Hainault in Belgium, not far from the French frontier, and flows S.W. through the departments of Nord, Aisne, Oise, and Seine-et-Oise, until it joins the Seine about 12 miles below Paris. Its whole length is 137 miles; and it is navigable as far as Chaunay 75 miles above its confluence with the Seine. It receives from the left the Serre, the Lette, the Aisne, and the Nonette; and from the right none but small streams, of which the most considerable is the Thérain. A small portion of the west of the department is

VOL. XVI.

watered by the Epte, a tributary of the Eure; and the S.E. corner is traversed by the Ourcq, which joins the Seine above Paris. The geological formation of the country is in general calcareous; and the soil in many parts fertile, consisting of a stiff clay; but in some places dry sandy tracts occur, which are entirely barren, or nearly so. Most of the land is well fitted for the cultivation of wheat or other kinds of corn; but the higher regions are chiefly used for pasture; and a great part of the country is covered with wood. The climate is not insalubrious, but rather moist, especially during the long winters. The mineral productions are few and of little consequence, except limestone, which is extensively worked. Small quantities of iron of an indifferent quality are also found. The extent of arable land in the department is estimated at about 960,000 acres: of meadow land, 74,000 acres; of vineyards, 6000 acres; of wood, 200,000 acres; of waste land, 37,000 acres. Corn, pulse, potatoes, and beet-root are produced in sufficient abundance to form articles of export; and hemp, flax, fruits for cider, &c., are also raised. The wine produced in Oise is bad; and the number of vineyards is decreasing. Cattle and horses are reared in the department, but not to any great extent; and the greatest amount of attention is de-

3 R

Oka.
||
O'Keeffe.

voted to the sheep, which are in general of an excellent breed. There are in Oise about 100,000 head of cattle, 60,000 horses, 600,000 sheep, 50,000 pigs, 1500 goats, 2500 mules, and 8000 asses. Manufactures of various kinds are carried on to a large extent. Among the most important is that of beet-root sugar; but there are also manufactured broad cloth, bricks, tiles, pottery, porcelain, leather, cordage, paper, beer, glass, and other articles. The trade is considerable in the produce of the manufacturing industry, and in grain, fruits, cider, and timber. The means of internal communication consist of the three rivers, Oise, Aisne, and Ourcq, navigable in this department for 82 miles; two canals, 21 miles in length; a railway traversing the department for 43 miles; and numerous roads. Oise forms the diocese of the Bishop of Beauvais; includes 4 courts of primary jurisdiction, 2 courts of commerce, 3 communal colleges, and 841 primary schools. It returns three members to the legislative assembly. The capital is Beauvais, and the department is divided into four arrondissements as follows:—

	Cantons.	Communes.	Pop. (1856).
Beauvais.....	12	216	128,721
Clermont.....	8	145	89,413
Compiègne.....	8	149	95,002
Senlis.....	7	126	82,949
Total.....	35	636	396,085

OKA, a river of European Russia, rises in the government of Orel, and flows N.E. through those of Tula, Kaluga, Moscow, Riazan, Vladimir, and Nijni-Novgorod. After a course of about 600 miles, it falls into the Volga at the town of Nijni-Novgorod. It is navigable as far as Orel, and is of great commercial importance, as affording an easy means of communication for the produce of the different regions on its banks. The country that it waters is the most fertile portion of the Russian empire, and has an area of 127,000 square miles. It receives numerous tributaries; of which the most important are the Upa, Jizdra, Nara, Moskva, Tzna, and Kliasma.

OKAMANDAL, a small district of British India, in the presidency of Bombay, and province of Guzerat, forming the north-western portion of the peninsula of Kattywar. It is separated from the mainland by a *runn* or salt marsh, extending from the Gulf of Cutch, in a S.W. direction to Mudhe, where it is separated from the sea by a narrow sand-bank, which is altogether covered during high tides. The area of the district is estimated at 334 square miles; and the length of the coast-line is about 75 miles. The north-western extremity forms a bold headland, which is indented on the N. side by the harbour of Beyt, protected by an island of the same name at its mouth. This district, on account of its favourable situation for molesting the commercial navigation of the Indian Ocean, was for a long time a favourite haunt of pirates; but their lawless depredations have been completely put down by the British government. The soil of Okamandal is quite barren; and the only articles of commerce yielded by the district are the *sankh* or conch-shells, which were formerly used as war trumpets by the Rajpoots; but their principal use is now by the Brahmins for religious purposes. The district contains 43 villages, and a population estimated at 12,590.

O'KEEFFE, JOHN, a popular dramatist, was born at Dublin in 1747. Though educated for a painter, he exhibited from an early age a decided passion for the drama. At the age of sixteen he had composed a play; at the age of eighteen he wrote a comedy, which was acted on the stage; and shortly afterwards he became a member of the company of the Smock-alley Theatre, Dublin. His active brain, however, did not find scope enough in the position of a mere player. While performing at the Irish capital, or strolling during the summer through the provinces, he pro-

duced several little pieces which met with success on the stage. At length, in 1778, his farce entitled *Tony Lumpkin in Town*, was played with applause at the Haymarket; and the career of a dramatist was opened up to O'Keeffe. Abandoning the profession of an actor, and settling in London in 1781, he commenced, amid an increasing attack of blindness, to support his family by his pen. Comedies and operatic farces followed each other in quick succession, and were variously brought out by Colman of the Haymarket, and Harris of Covent Garden. Their genial and vivacious sentiment, and broad and whimsical humour, atoned for their poverty of incident and want of individual characters; the great majority of them had a long run of success; and many of them were acted over again at the command of Royalty. It was about 1798 that O'Keeffe, then almost blind, ceased to have connection with the stage. The rest of his life was spent under pecuniary embarrassments. An edition of 21 of his plays, which was published in 1798, scarcely paid the expenses; and a small annuity, which he bought in 1800, and two royal pensions, which were respectively conferred upon him in 1803 and 1826, afforded him but an inconsiderable pittance. His death took place at Southampton in 1833. O'Keeffe, during his long life, had produced no fewer than 68 plays. Of these, *Wild Oats*, *The Agreeable Surprise*, *The Poor Soldier*, *The Highland Reel*, and some others, still retain their footing on the stage. (*Recollections of the Life of John O'Keeffe, written by himself*, in 2 vols. London, 1826.)

OKEN, LORENZ. Under this name the great naturalist of the transcendental or deductive school is commonly known; but his real name was "Lorenz Ockenfuss," under which he was baptized at Bohlsbach, Würtemberg, being born in that small Suabian village on the 1st of August 1779. As "Ockenfuss" he was entered at the natural history and medical classes in the university of Würzburg; whence he proceeded to that of Göttingen, where he became a private teacher, and abridged his name to "Oken." As Lorenz Oken, he published, in 1802, his small work entitled *Grundriss der Naturphilosophie, der Theorie der Sinne, und der darauf gegründeten Classification der Thiere*, 8vo.

This is the first of the series of works which placed Oken at the head of the "natur-philosophie" or physio-philosophical school of Germany. In it he extended to physical science the philosophical principles which Kant had applied to mental and moral science. Oken had, however, in this application, been preceded by Fichte, who, acknowledging that the materials for a universal science had been discovered by Kant, declared that nothing more was needed than a systematic co-ordination of these materials; and this task Fichte undertook in his famous *Doctrine of Science* (*Wissenschafts-lehre*), the aim of which was to construct *a priori* all knowledge. In this attempt, however, Fichte did little more than indicate the path; it was reserved for Schelling fairly to enter upon it, and for Oken, following him, to explore its mazes yet farther, and to produce a systematic plan of the country so surveyed.

In the *Grundriss der Naturphilosophie* of 1802, Oken sketched the outlines of the scheme he afterwards devoted himself to perfect. The position advanced in that remarkable work, and to which he ever after professed himself to adhere, is this,—“that the animal classes are virtually nothing else than a representation of the sense-organs, and that they must be arranged in accordance with them.” Agreeably with this idea, Oken contends that there are only five animal classes:—1. The *Dermatozoa*, or Invertebrata; 2. the *Glossozoa*, or Fishes, as being those animals in which a true tongue makes, for the first time, its appearance; 3. the *Rhinozoa*, or Reptiles, wherein the nose opens for the first time into the mouth and inhales air; 4. the *Otozoa*, or Birds, in which the ear for the first time opens

Oken.

Oken. externally; and 5. the *Ophthalmozoa*, or mammals, in which all the organs of sense are present and complete, the eyes being movable and covered with two lids.

In 1805 Oken made another characteristic advance in the application of the *a priori* principle, by a book *On Generation* (*Die Zeugung*, Frankf., 8vo), wherein he maintained the proposition "that all organic beings originate from, and consist of, *vesicles* or *cells*. These vesicles, when singly detached and regarded in their original process of production, are the infusorial mass or *protoplasma* (*urschleim*), from whence all larger organisms fashion themselves, or are evolved. Their production is therefore nothing else than a regular agglomeration of infusoria; not, of course, of species already elaborated or perfect; but of mucous vesicles or points in general, which first form themselves by their union or combination into particular species."

This doctrine is strikingly analogous to the generalized results of the ablest microscopical observations on the development of animal and vegetable tissues which have been prosecuted of late years.

One year after the production of this remarkable treatise, Oken advanced another step in the development of his system; and in a volume published in 1806, in which Keiser assisted him, entitled, *Beitragen zur Vergleichenden Zoologie, Anatomie, und Physiologie*, he demonstrated that the intestines originate from the umbilical vesicle, and that this corresponds to the vitellus or yolk-bag. Caspar Friedrich Wolff had previously proved this fact in the chick;¹ but he did not see its application as evidence of a general law. Oken showed the importance of the discovery as an illustration of his system. In the same work Oken described and re-called attention to the *corpora Wolffiana*, or "primordial kidneys," as they are now termed and recognised. At this period, the enlightened Duke of Weimar and the poet Goethe (who repaid the friendship of his prince by the reflection of his own undying renown), were bringing to perfection the plan of general education for the grand-duchy. The university of Jena, under these auspices, had been rapidly rising to pre-eminence; not through the wealth of its endowments or by any artificial excitement, but through the celebrity of the professors and members, whose noble aspirations were stimulated by the encouraging eye of the prince, and the observant care of his minister for education. Under these auspices had been fostered a Griesbach, Fichte, Schelling, Feuerbach, the two Humboldts, Hufeland, and Schlegel.

The reputation of the young *privat-docent* of Göttingen had reached the ear of Goethe, and in 1807 Oken was invited to fill the office of "Extraordinary Professor of the Medical Sciences" in the university of Jena. He accepted the call, and selected for the subject of his "Inaugural discourse," his ideas on the "Signification of the bones of the skull," based upon a discovery he had made in the previous year. This famous lecture was delivered in the presence of Goethe, as privy-councillor and rector of the university, and was published by the young professor in the same year, with the title, *Ueber die Bedeutung der Schädelknochen, ein Programm beim Antritt der Professur an der Gesamt-Universität zu Jena*, 4to, 1807. Of the relation of this essay to the vertebral theory of the skull, we shall subsequently offer a few remarks.

With regard to the origin of the idea, Oken narrates in his *Isis*, that, walking one autumn-day in 1806, in the Hartz forest, he stumbled upon the blanched skull of a deer, picked up the partially dislocated bones, and, contemplating them for a while, the truth flashed across his mind, and he exclaimed, "It is a vertebral column!" At a meeting of the German naturalists, held at Jena, some years afterwards, Professor Kieser gave an account of Oken's dis-

covery in the presence of the grand-duke, which account is printed in the *Tageblatt*, or "proceedings," of that meeting. The professor states that Oken communicated to him his discovery when journeying in 1806, to the Isle of Wangeroog. On their return to Göttingen, Oken explained his ideas by reference to the skull of a turtle in Kieser's collection, which Oken disarticulated for that purpose with his own hands. "It is with the greatest pleasure," writes Kieser, "that I am able to show here the same skull, after having it thirty years in my collection. The single bones of the skull are marked by Oken's own hand-writing, which may be so easily known." There was a cause, as we shall presently see, for this circumstantial testimony.

Oken having delivered and printed his *Introductory Lecture* in 1807, informs us, in the heft vii. of his *Isis*, that he presented copies to Goethe and to other members of the grand-duke's government. "Goethe was so pleased with my discovery as to invite me to stay with him during the Easter week of 1808 in his house at Weimar, which invitation I accepted."

The range of Oken's lectures at Jena was a wide one, and they were highly esteemed. They embraced the subjects of natural philosophy, general natural history, zoology, comparative anatomy, the physiology of man, of animals, and of plants. The spirit with which the professor grappled with the vast scope of science is characteristically illustrated in his essay *Ueber das Universum als Fortsetzung des Sinnessystems*, 4to, 1808. In this work he propounds "that organism is none other than a combination of all the universe's activities within a single individual body." This doctrine led him to the conviction "that world and organism are one in kind, and do not stand merely in harmony with each other."

In the same year he published his *Erste Ideen zur Theorie des Lichts, &c.*, in which he advanced the proposition, that "light could be nothing but a polar tension of the ether, evoked by a central body in antagonism with the planets; and that heat was none other than the motion of this ether." Here Oken may be said to have anticipated the doctrine of the "correlation of physical forces."

In 1809, he extended his system to the mineral world, arranging the ores, not according to the metals, but agreeably to their combinations with oxygen, acids, and sulphur. In 1810 Oken summed up his several views on organic and inorganic natures into one compendious system. The first edition of his *Lehrbuch der Naturphilosophie* appeared in that and the following years, in which he sought to bring his several doctrines into mutual connection, and to "show that the mineral, vegetable, and animal kingdoms are not to be arranged arbitrarily in accordance with single and isolated characters, but to be based upon the cardinal organs or anatomical systems, from which a firmly-established number of classes would necessarily be evolved; that each class, moreover, takes its starting point from below, and consequently that all of them pass parallel to each other." That, "as in chemistry, where the combinations follow a definite numerical law, so also in anatomy, the organs—in physiology, the functions—in natural history, the classes, families, and even genera of minerals, plants, and animals—present a similar arithmetical ratio."

Three editions of this extraordinary book have appeared, each more fully elaborated than the former. An epitome of the work will presently be given. In continuing the personal history of the author of the *Naturphilosophie*, we may first mention that, on Goethe's recommendation, Oken was honoured, on the publication of the first edition of the *Lehrbuch* in 1810, with the title of "Hof-rath," or court-councillor. In 1812 he was appointed "ordinary professor of natural sciences" in the university of Jena."

¹ *Theoria Generationis*, 8vo, 1774.

Oken.

In 1816 he commenced the publication of his well-known periodical, entitled *Isis, ein Encyclopädische Zeitschrift, vorzüglich für Naturgeschichte, vergleichende Anatomie und Physiologie*, 4to. In this journal not only appeared essays and notices on the natural sciences, but on other subjects of interest; poetry, and even comments on the politics of other German states, were occasionally admitted. This led to representations and remonstrances from the governments criticized or impugned, and the court of Weimar gave Oken the alternative of suppressing the *Isis*, or of resigning his professorship. He chose the latter. The publication of the *Isis* at Weimar was prohibited. Oken made arrangements for its issue at Rudolstadt, and this continued uninterruptedly until the year 1848.

The independent spirit manifested by Oken excited his courtly enemies to harsher measures. An accusation was preferred against Oken as a member of a forbidden "secret democratic society;" he stood his trial and was acquitted. He thereupon retired for a while into private life, occupying himself with the editorship of the *Isis*, and with his scientific works. Amongst these may be cited the *Lehrbuch der Naturgeschichte*, 1815-1825; his *Handbuch der Naturgeschichte zum Gebrauch bei Vorlesungen*, 1816-1820; and his *Naturgeschichte für Schulen*, 8vo, 1821. In these manuals Oken considered that he had arranged for the first time the genera and species in accordance with the only true or physio-philosophical principles; stating briefly everything of vital importance respecting them; and that it was the first attempt to frame a truly scientific history of nature.

In 1821 Oken promulgated, in his *Isis*, the first idea of the annual general meetings of the German naturalists and medical practitioners, which happy idea was realized in the following year, when the first meeting was held at Leipzig in 1822. They have been continued ever since in Germany; and similar annual scientific gatherings have been adopted in other countries, of which the "British Association for the Advancement of Science" is an instance, avowedly, at its origin, organized after the German or Okenian model. The writer of the present notice attended the German annual meeting at Freiburg in 1838, and heard a fervid extempore address by Oken of upwards of an hour's duration, in which the rare eloquence of the gifted man, and the sympathy and respect of his countrymen for the orator, were strikingly manifested.

In 1828 Oken resumed his original humble duties as "private teacher" in the newly-established university of Munich; and soon afterwards he was appointed "ordinary professor" in the same university. In 1832, on the proposition by the Bavarian government to transfer Oken to a professorship in a provincial university of the state, he resigned his appointments and left the kingdom.

Switzerland has the honour of affording the final place of refuge, with means of an independent pursuit of science, to this philosophic and patriotic naturalist. Oken was appointed in 1833 to the professorship of natural history in the then recently-established university of Zurich. There he continued to reside, fulfilling his professional duties and promoting the progress of his favourite sciences, to the period of his demise, in the seventy-second year of his age.

Oken's philosophy.

In his *Lehrbuch der Naturphilosophie*, of which a translation of the last edition, by A. Tulk, Esq., has been published by the Ray Society, under the title of *Elements of Physio-philosophy*, Oken begins by asserting that philosophy, as the science which embraces the principles of the universe or world, is only a logical conception; but it may conduct to the real conception. Thus the mathematics are principles (or a philosophy) of which the universe is the reality. "The world consists of two parts—one apparent, real, or material; the other non-apparent, ideal, spiritual. Hence there are two divisions of philosophy,—viz., pneumato- and physio-philosophy."

The latter is the subject of this treatise.

Its object is "to show how, and in accordance with what

laws, the material took its origin; to portray the first periods of the world's development from nothing; how the elements and heavenly bodies originated; in what method by self-evolution into higher and manifold forms they separated into minerals, became finally organic, and in man attained self-consciousness." Physio-philosophy is, therefore, in fact, the history of creation, a name under which it was taught by the most ancient philosophers,—viz., as "cosmogony."

Man, being the crown of nature's development, must comprehend every thing that has preceded him. "In a word, man must represent the whole world in miniature." Hence the laws of spirit are not different from the laws of nature—both are transcripts of each other.

Physio-philosophy, therefore, is more important than pneumato-philosophy, because nature is antecedent to the human spirit.

And the whole of philosophy consists in the demonstration of the parallelism that exists between the activities of nature and of spirit.

But inasmuch as the spiritual existed before the real, and gave it birth, physio-philosophy must commence from the spirit.

It is divided into three parts: the *first*, treating of spirit and its activities; the *second*, of the individual phenomena or things of the world; the *third*, of the continuous operation of spirit in the individual things.

It would be impossible, within the limits of this article, to follow Oken through his extraordinary development of the science he has thus described. Every sentence is a link in the chain of argument, which could not be extracted so as to be intelligible, nor would it endure further condensation. It must suffice to state that he traces, agreeably with his system, the evolutions of every form of being, organic and inorganic, in a regular series, from the simple element to the most complex shapes. "Polarity is the first force which appears in the world." "Galvanism is the principle of life," "the vital force." "The galvanic process," he says, "is one with the vital process." "There is no other vital force than the galvanic polarity." Oken, then, contends that organism is galvanism, residing in a thoroughly *homogeneous mass*. A galvanic pile, pounded into atoms, must become alive. In this manner nature brings forth organic bodies. The basis of electricity is the air; of magnetism, metal; of chemism (the name he gives to the influence that produces chemical combination), salts. The basis of galvanism, in like manner, is the organic mass. Accordingly, whatever is organic is galvanic; whatever is alive is galvanic. Life, organism, galvanism, are one. Life is the vital process; the vital process is an organic or galvanic process. Galvanism is the basis of all the processes of the organic world.

At the creation God created a mass of organisms of no larger size than an infusorial point. Whatever is larger has not been created but developed. "So," says Oken, "the Bible teaches us." God did not make man out of nothing, but took an elemental body then existing, an earth-clod or carbon, moulded it into form, thus making use of water, and breathed into it life,—viz., air, whereby galvanism or the vital process arose."

Organization is produced by the co-operating influence of light and heat. "The ether imparts the substance, the heat the form, the light the life."

The life of an inorganic body is a threefold action of the three terrestrial elements, in which three processes galvanism consists. The *nutrient* process is magnetic, present and entire in every part of the body, and wheresoever it is withdrawn there is death. It operates according to the laws of crystallization. The *digestive* process acts according to the laws of chemism, which is not only the process of liquefaction, but the process of formation or creation of new organic matter. The digestive process converts the inorganic to the organic mass. It is the formation of mucus. The chyle is strictly a mucus. Into mucus the air finally settles down by the process of oxidation, called the *respiratory* process. By this the juices emerge from their state of indifference, by which each point of the juice becomes polar towards every other; all are mutually attracted, all repelled, and thereby a decided circulation-motion is originated.

Every globule of sap or mucus is *per se* indifferent. It has, therefore, a natural affinity for each of the three elements comprehended in the organism. By respiration it is united

Oken.

Oken. to the element air, by digestion to the element water, by nutrition to the element earth. These three processes constitute the galvanic process. Thus the galvanic circle is complete, and motion is the manifestation of galvanism. The process of motion is synonymous with the galvanic process—this is the vital process.

The distinction between the organic and the inorganic is self-motion. The organic is destroyed so soon as motion disappears in it; the inorganic is destroyed so soon as motion enters it.

The above will serve as an idea of the spirit of the work, and of the author's style and treatment of the most recondite questions. We now return to Oken's essay on the *Signification of the Bones of the Head*, on which, perhaps, his reputation as an original discoverer is best founded.

There nevertheless still prevails confusion, or indistinctness of ideas, in the opinions set forth relative to Oken's claims to, or share in, the discovery of the vertebral nature and arrangement of the bones of the skull.

All Oken's writings are eminently deductive illustrations of a foregone and assumed principle, which, with other philosophers of the transcendental school, he deemed equal to the explanation of all the mysteries of nature.

According to Oken, the head was a repetition of the trunk—a kind of second trunk, with its limbs and other appendages; this sum of his observations and comparisons—few of which he ever gave in detail—ought ever to be borne in mind in comparing the share taken by Oken in homological anatomy with the progress made by other cultivators of that philosophical branch of the science.

The idea of the analogy between the skull, or parts of the skull, and the vertebral column, had been previously propounded and ventilated in their lectures by Autenreith and Kilmeyer, and in the writings of Jean-Pierre Frank. By Oken it was applied chiefly in illustration of the mystical system of Schelling—the *all-in-all* and *all-in-every-part*. From the earliest to the latest of Oken's writings on the subject, "the head is a repetition of the whole trunk with all its systems. The brain is the spinal chord; the cranium is the vertebral column; the mouth is intestine and abdomen; the nose is the lungs and thorax; the jaws are the limbs; and the teeth the claws or nails." Spix, in his folio *Cephalogenesis*, 1818, richly illustrated comparative craniology, but presented the facts under the same transcendental guise; and Cuvier ably availed himself of the extravagancies of these disciples of Schelling to cast ridicule on the whole inquiry into those higher relations of parts to the archetype, which Professor Owen has called "general homologies." "M. Spix," Cuvier writes, "makes this bone, which I call 'posterior frontal,' the 'scapula' of the upper limb of the head; and M. Oken, according to the same mystical language, makes it the 'merry thought' (*fourchette*) of the upper limb of the head; for it must be remarked, that the *Philosophy of Nature*, in pretending to find again in the head all the parts of the trunk, acts so arbitrarily, that each of those who would apply it employ these strange denominations in a different manner." "Cet *humerus de la tête* de M. Oken devient pour M. Spix le *pubis* de cette même tête, ou, pour parler un langage intelligible, un des osselets de l'ouïe."¹

The vertebral theory of the skull had practically disappeared from anatomical science when the labours of Cuvier drew to their close. It needs only to refer to the works of his chief pupils and successors, Milne-Edwards, John Müller (*Physiologie*), Wagner (*Lehrbuch der Zootomie*), or Agassiz (*Poissons Fossiles*), to have sufficient evidence of that fact. In Owen's *Archetype and Homologies of the Vertebrate Skeleton*, the idea of the vertebral structure of the skull was not only revived but worked out for the

first time inductively, and the theory rightly stated, as follows:—"The head is not a virtual equivalent of the trunk, but is only a portion, i.e., certain modified segments of the whole body. The jaws are the 'hæmal arches' of the first two segments; they are not limbs of the head."—(P. 176.)

Vaguely and strangely, however, as Oken had blended the idea with his *à priori* conception of the nature of the head, the chance of appropriating it seems to have overcome the moral sense—the least developed element in the spiritual nature—of Goethe, unless the poet deceived himself.

Comparative osteology had early attracted Goethe's attention. In 1786 he published his essay *Ueber den Zwischenkiefer den des Menschen und der Thiere*, 4to, Jena, showing that the intermaxillary bone existed in man as well as in brutes. Not a word in this essay gives the remotest hint of his having then possessed the idea of the vertebral analogies of the skull.

In 1820 (*Morphologie*, i., 2, p. 250), Goethe first publicly stated that thirty years before the date of that publication he had discovered the secret relationship between the vertebræ and the bones of the head, and that he had always continued to meditate on this subject. The circumstances under which the poet, in 1820, narrates having become inspired with the original idea, are suspiciously analogous to those described by Oken in 1807, as producing the same effect on his mind. A bleached skull is accidentally discovered in both instances; in Oken's it was that of a deer in the Harz Forest; in Goethe's it was that of a sheep picked up on the shores of the Lido, at Venice. Mr Buckle, in his discourse "On the Influence of Women in the Progress of Knowledge"—*Fraser's Magazine*, April 1858, p. 402, states:—"Goethe, strolling in a cemetery near Venice, stumbled upon a skull which was lying before him. Suddenly the idea flashed across his mind that the skull was composed of vertebræ; in other words, that the bony covering of the head was simply an expansion of the bony covering of the spine. This luminous idea was afterwards adopted by Oken and a few other great naturalists in Germany and France, but it was not received in England till ten years ago, when Mr Owen took it up, and in his very remarkable work on the *Homologies of the Vertebrate Skeleton*, showed its meaning and purpose as contributing towards a general scheme of philosophic anatomy." This reproduction of a disparaging statement respecting Oken necessitates the following summary of the facts:—

It may be assumed that Oken, when a private teacher at Göttingen in 1806, knew nothing of this unpublished idea or discovery of Goethe; and that Goethe first became aware that Oken had the idea of the vertebral relations of the skull when he listened to the *Introductory Discourse* in which the young professor, invited by the poet to Jena, selected this very idea for its subject. It is incredible that Oken, had he adopted the idea from, or been aware of an anticipation by, Goethe, should have omitted to acknowledge the source—should not rather have eagerly embraced so appropriate an opportunity of doing graceful homage to the originality and genius of his patron.

The anatomist having lectured for an hour, plainly unconscious of any such anticipation, it seems hardly less incredible that the poet should not have mentioned to the young lecturer his previous conception of the vertebral theory, and the singular coincidence of the accidental circumstance which he subsequently alleged to have produced that discovery. On the contrary, Goethe permits Oken to publish his famous lecture, with the same unconsciousness of any anticipation as when he delivered it; and Oken, in the same state of belief, transmits a copy to Goethe, who thereupon honours the professor with special marks of atten-

¹ *Ossemens Fossiles*, 4to, 1824, tom. v., pt. ii., pp. 75-85, quoted in an able article in the *Quarterly Review*, vol. xcii., in which the history of the Discoveries of the Archetype and Homologies of the Vertebrate Skeleton is briefly but convincingly discussed, pp. 70-80.

Oken. tion, and an invitation to his house. No hint of any claim of the host is given to the guest; no word of reclamation in any shape appears for some years. In Goethe's *Tag und Jahres Hefte*, he refers to two friends, Riemer and Voigt, as being cognizant in 1807, of his theory. Why did not one or other of these make known to Oken that he had been so anticipated? "I told my friends to keep quiet," writes Goethe in 1825! Spix, in the meanwhile, in 1815, contributes his share to the development of Oken's idea in his *Cephalogenesis*. Ulrich follows in 1816 with his *Schildkrotenschädel*; next appears the contribution, in 1818, by Bojanus, to the vertebral theory of the skull; amplified in the *Paragon* to that anatomist's admirable *Anatome Testudinis Europææ*, fol., 1821. And now, for the first time in 1818, Bojanus, visiting some friends at Weimar, there hears the rumour that his friend Oken had been anticipated by the great poet. He communicates it to Oken, who, like an honest man, at once published the statement made by Goethe's friends in the *Isis* of that year (see p. 509), offering no reflection on the poet, but restricting himself to a detailed and interesting account of the circumstances under which he himself had been led, independently, to make his discovery, when wandering in 1806 through the Hercynian forest. It was enough for him thus to vindicate his own claims; he abstains from any comment reflecting on Goethe; and maintained the same blameless silence when Goethe ventured for the first time to claim for himself, in 1820, the merit of having entertained the same idea, or made the discovery, thirty years previously. Such an idea may have occurred to him at that time; in 1807 Goethe may have determined to keep silence on the matter, and have permitted Oken to reap undisturbed the honour of the discovery; for the poet must then, at least, have been convinced that the young professor had made it independently. But this generous hypothesis is incompatible with Goethe's later reclamation. In this he not only ascribes the discovery to himself, but writes, "In the year 1807 this theory appeared tumultuously and imperfectly before the public." By "tumultuously" Goethe signifies his recollection of the applause with which Oken's audience received the first announcement of the theory. What is worse, Goethe apathetically permitted, to say the least, some of his worshippers to undermine the moral character of Oken in reference to this cranio-vertebral hypothesis.

In 1836 an anonymous statement appeared in the *Allgemeine Zeitung*, to the effect that Oken had stolen the idea of the vertebral nature of the skull from Goethe. Oken, with German bluntness, replied in the same journal, that his nameless accuser "was a liar and calumniator."¹ The accuser was silent.

The German naturalists held their annual meeting that year at Jena, and there Professor Kieser publicly bore testimony, from personal knowledge, to the circumstances and dates of Oken's discovery. Neither Goethe nor any of his friends had a word to offer on the subject. Yet the poet continued to permit his flatterers from time to time to ascribe to him the merit of the discovery; and again, in 1824, he claimed it for himself, with the contemptuous allusion, above cited, to the *Introductory Lecture* of 1807, but without mentioning Oken's name. Goethe did not dare directly to impute plagiarism to Oken, who thereupon consistently kept silent. At length, in the edition of Hegel's works by Michelet, 8vo, Berlin, 1842, there appeared the following paragraph, p. 567:—"The type-bone is the dorsal vertebra, provided inwards with a hole, and outwards with processes, every bone being only a modification of it. This idea originated with Goethe, who worked it out in a treatise written in 1785, and published it

in his *Morphologie*, 1820, p. 162. Oken, to whom the treatise was communicated, has pretended that the idea was his own property, and has reaped the honour of it." This accusation again called out Oken, who thoroughly refuted it in an able, circumstantial, and temperate statement, in heft vii. of the *Isis*, 1847. Goethe's osteological essay of 1785, and the only one he printed in that century, is on a different subject. In the *Morphologie* of 1820-24, Goethe distinctly declares that he had never published his ideas on the vertebral theory of the skull. He could not, therefore, have sent any such essay to Oken before the year 1807. Oken, in reference to his previous endurance of Goethe's pretensions, states, that "being well aware that his fellow-labourers in natural science thoroughly appreciated the true state of the case, he confided in quiet silence in their judgment. Meckel, Spix, Ulrich, Bojanus, Carus, Cuvier, Geoffroy St Hilaire, Albers, Straus-Durckheim, Owen, Kieser, and Lichtenstein, had recorded their judgment in his favour and against Goethe. But upon the appearance of the new assault in Michelet's edition of Hegel, he could no longer remain silent."

A recent biographer of Goethe asks, "why did not Oken make the charge of plagiarism during Goethe's lifetime?"² The answer is, that he at no time made such charge. He left Goethe's affirmations for what they were worth, and to produce such effect as they might with the competent historians of science. It was possible that Goethe had stated a truth: he might only have been uncandid and ungenerous. But that did not make Oken the less an original discoverer. Only when he was charged with plagiarism did he enter into the question with the view of honest self-vindication, and that both before and after Goethe's death.

As to the question of the superiority of the deductive over the inductive method in philosophy, as illustrated by the writings of Oken. His bold axiom, that heat is but a mode of motion of light,—and the idea broached in his essay on *Generation* (1805), viz., that "all the parts of higher animals are made up of an aggregate of infusoria or animated globular monads,"—are both of the same order as his proposition of the head being a repetition of the trunk, with its vertebræ and limbs. Science would have profited no more from the one idea without the subsequent experimental discoveries of Oersted and Faraday; or by the other without the microscopical observations of Brown, Schleiden, and Schwann; than from the third notion without the inductive demonstration of the segmental constitution of the skull by Owen.

It is questionable, indeed, whether in either case the discoverers of the true theories were excited to their labours, or in any way influenced, by the *à priori* guesses of Oken; more probable is it that the requisite researches and genuine deductions therefrom, were the results of the correlated fitness of the stage of the science, and the gifts of its true cultivators at such particular stage.

Oken's real claims to the support and gratitude of naturalists rest on his appreciation of the true relations of natural history to intellectual progress, of its superior teachings to the mere utilitarian applications of observed facts, of its intrinsic dignity as a science.

To natural history thus worthily comprehended Lorenz Oken devoted his whole time and energies up to his last illness, which closed his career at Zurich, on the 11th of August 1851. A fine statue of the philosopher, by Drake of Berlin, has been erected to his honour in the university of Jena, where he first publicly taught.

We give a list of Oken's chief works and original essays:

1. Grundriss der Naturphilosophie, der Theorie der Sinne und der darauf gegründeten Classification der Thiere. Frankf. 1802, 8°. 2. Die Zeugung. Frankf. 1805, 8°. 3. Abriss

Okhotsk
||
Oldcastle.

(R. O.)

OKHOTSK, a town and province of Eastern Siberia, in the district of Yakutsk. The province consists of a narrow strip of country, along the shore of the sea of Okhotsk, about 1000 miles in length, and varying from 80 to 200 in breadth. It is traversed through its whole extent by the Stanovoi Mountains, which run along the sea coast, and send down a few small streams to the sea. Of these the chief is the Okhota. The climate is very severe; but there are some tracts of pasture-ground and clumps of trees. The rein-deer and the dog are the only tame animals; and furs and timber are the only articles of produce. Fish is obtained along the coasts; and shoals of small whales are occasionally met with. The district is used as a penal settlement for the most incorrigible criminals, with whom and their descendants it is for the most part peopled. Pop. about 7000. The town of Okhotsk stands at the mouth of the Okhota. N. Lat. 59. 21., E. Long. 142. 45. It consists of a collection of ill-built and irregularly arranged log-houses; and has a government house, hospital, church, storehouses, &c. It is the principal station of the Russo-American trading company, who convey furs hither from America, and hence to Kiachta, to exchange for Chinese goods. Pop. 957.

OKHOTSK, *Sea of*, an inlet of the North Pacific Ocean, between Kamtschatka and Siberia, extending from N. Lat. 50. to 60., E. Long. 137. to 155. From its N. E. extremity the gulfs of Ijghinsk and Perjinsk stretch into the land. Its depth is generally great, and there are few islands. Near the coast it is frozen for 6 months of the year.

OLAND, or OEELAND, an island in the Baltic, belonging to Sweden, included in the lan of Kalmar, and separated from the mainland by the Kalmar Sound, which varies from 3 to 15 miles in breadth. Length 85 miles; average breadth 8; area 608 square miles. The western shores are low; those to the east high and steep; and the prevalent formation throughout the island is limestone. To the north are a few small lakes; but no considerable streams anywhere occur. The soil, though scanty, is fertile; and a great part of the surface is covered with fine forests. Cattle and sheep are extensively reared; and deer, wild boars, and other game abound. Öland is famous for its breed of ponies of very small size. The weaving of cloth is carried on, and furnishes an article of export trade. The island contains several villages, of which Borgholm the capital, on the west coast, is the chief. The people are extensively employed in fishing and navigation; and there is an alum mine, the most important in the kingdom, which employs about 300 hands. Pop. 33,000.

OLDCASTLE, SIR JOHN, commonly called "The good LORD COBHAM," was born in the fourteenth century, during the reign of Edward III. He obtained his peerage by marrying the heiress of Lord Cobham, who had distinguished himself during the reign of Richard II. for his opposition to the tyranny of that monarch. He commanded an English army in France during the reign of Henry IV. where he displayed great military skill. Oldcastle had, from the outset of his career, set himself with great patriotism and independence to oppose the political and ecclesiastical corruptions of his time. Being a man of fine natural talents, and having a passionate thirst for knowledge, he turned his attention to the doctrines of John Wycliffe; and after examining them with great care, declared his adherence to the cause of the reformers. He collected and transcribed the works of Wycliffe for circula-

tion among the people, and sent preachers of reform into various parts of the country. The cause made great progress, and the growth of heresy was attributed to this nobleman's influence. Henry V. had a partiality for the good lord, and tried to reclaim him by expostulation. "Next to God," said his lordship, "I profess obedience to my king; but as to the spiritual dominion of the Pope, I could never see upon what foundation it was claimed, nor can I pay him any obedience." The king turned away in displeasure, and left the heretic to the tender mercies of the Church. Escaping from the tower where he had been imprisoned as a heretic, he sought refuge in Wales. In 1414 the clergy got up a report of an imaginary conspiracy of the Lollards, with Lord Cobham at their head, for the destruction of the king. A bill of attainder was passed against him; 1000 merks were set upon his head; and perpetual exemption from taxes was promised to any town that should secure him. After an exile of four years in Wales he was at length seized, carried to London, and executed in St Giles' Field in the most cruel and barbarous manner. Johan Bale tells us in his *Breve Chronicle* of the examination and death of this nobleman: "Than was he hanged up there by the myddle in cheanes of yron, and so consumed a lyve in the fyre, praysynge the name of God so longe as his lyfe lasted" (p. 96). Thus died in 1418 one of the ablest and most brilliant men of his day, who, according to his biographers, was qualified to shine alike in the cabinet, the field, and the court. As a writer Lord Cobham is known by a piece entitled *Twelve Conclusions Addressed to the Parliament of England*. He thus stands distinguished as the first martyr and the first author among the nobility of England. (See *Lives of Wycliffe and his Disciples*, by William Gilpin, 1765.) Capgrave, in his *Chronicle of England* (edited by the Rev. F. C. Hingeston, London, 1858), gives a tolerably minute account of the career of Oldcastle; but with a strong prejudice against him and all Lollards. The priestly chronicler remarks of his lordship: "A strong man in bataile he was, but a grete heretik, and a gret enmye to the Chérch" (p. 304).

OLDCASTLE, a market-town of Ireland, county of Meath, 20 miles N.W. of Trim, and 52 N.W. of Dublin. It has three churches, a market-house, savings-bank, dispensary, school, and poorhouse. There are here lime-quarries, and extensive flour-mills; and an active trade is carried on in yarn. Pop. 1072.

OLDENBURG, GRAND DUCHY OF, one of the states of the German Confederation, consists of three parts, separated from one another by other states. The duchy of Oldenburg properly so called, is bounded on the N. by the German Ocean, E. by Hanover and the territory of Bremen, S. and W. by Hanover; and lies between N. Lat. 52. 50. and 53. 44., and E. Long. 7. 40. and 8. 45. The principality of Lübeck or Eutin is bounded by the duchy of Holstein, the territory of the free city Lübeck, and the Baltic. The principality of Birkenfeld, which forms the third portion of Oldenburg, lies in Southern Germany; and is bounded N. and W. by Rhenish Prussia, S. and E. by Coburg and Hesse-Homburg. Total area, 2433 square miles. The surface of Oldenburg proper is level throughout, as it forms part of the great plain of Northern Germany. Its uniformity is only here and there broken by low sand-hills, such as the Osenberge, between the towns of Oldenburg and Delmenhorst. The land on the coasts of the North Sea and on the banks of the Weser and Jahde is low, rich, and marshy; and is protected by embankments from the incursion of the water. The inland regions consist of moors and heaths. The sea-coast is lined with extensive sand-banks, called *Watten*. The principality of Lübeck is also for the most part flat and barren; but near the sea there are some rich and fertile districts.

Birkenfeld is a rocky and mountainous region, with numerous valleys of no great extent. The duchy of Oldenburg is washed by the German Ocean, which forms two gulfs, those of Jahde and Weser, at the mouths of the rivers of the same names; the principality of Lübeck is washed by the Baltic. The principal rivers in Oldenburg are the Weser, which forms its boundary on the side of Bremen and Hanover, and receives the Hunte with its tributary the Lethe, and the Ochtum with the Delme; the Hase and the Leda in the S., which join the Ems; and the Jahde, a small river near the coast. In the principality of Lübeck the Trave, a navigable river, and the Schwentine, both flow into the Baltic. In Birkenfeld the Nahe, an affluent of the Rhine, takes its origin. In Oldenburg and Lübeck there are numerous lakes, some of them of considerable size, but in Birkenfeld there are none. The most important in the duchy proper are the Zwischenahner-Meer, the Great and Little Bullenmeer, while Lübeck contains the Plöner-See, Eutiner-See, Keller-See, &c. The climate is temperate, but damp and foggy on account of the vicinity of the sea.
